Case Report

Eruptive xanthomas: Might be traditional hawthorn vinegar induced?

ABSTRACT

Eruptive xanthomas that are characterized by yellowish red papules results from hyperlipidemia, particularly hypertriglyceridemia. The hyperlipidemia responsible for this disorder can be caused by a primary genetic defect, a secondary disorder, or both. Some medications such as estrogen or retinoid treatments may cause eruptive xantomas by increasing serum lipids. We present a case eruptive xantomas triggered by hawthorn vinegar.

Keywords eruptive xanthomas, hawthorn, hyperlipidemia

A 38-year-old man attended with papular lesions on both forearms and back. The lesions began on extensor surfaces of forearms 10 days ago, subsequently spreading to his back. The patient described mild pruritus. There was hyperlipidemia in his and his family’s (his mother and uncle) medical history. He denied a family history for similar lesions. His previous levels of cholesterol and triglyceride were about 400 and 800 mg/dL respectively. He did not have history of using any drug for hyperlipidemia or another health problem. He told that he had begun to drink hawthorn vinegar 50 mL/day for three weeks.

Dermatological examination showed multiple pinkish-yellow papules over the extensor aspects of forearms and the back and some of them had lobulated appearance (Figs. 1-2).

His laboratory tests showed high levels of cholesterol (1320 mg/dL, N: < 200 mg/dL) triglyceride (8840 mg/dL, N: < 200 mg/dL) and blood glucose (393 mg/dL, N: 70 - 109 mg/dL). AST was 60 U/L (N: < 50U/L) ALT was 60 U/L (N: < 50U/L). Renal, and thyroid function tests and hemogram were within normal limits. The skin biopsy revealed foamy macrophages which have an eccentric nucleus and a large amount of cytoplasm infiltrating the dermis. They were stained with CD 68 (Figs. 3-4). Eruptive xanthoma was diagnosed with clinical, laboratory and pathological findings. He was consulted to endocrinology and hawthorn vinegar was stopped and diet for hyperlipidemia and hyperglycemia was suggested. Blood glucose level decreased to normal limit and lipid levels prominently diminished and the lesions improved in 1 week with only diet. It was thought that hawthorn vinegar might have triggered the increase of lipid and glucose levels on the base on familial hyperlipidemia in this patient.

Hyperlipidemia is classified in 2 groups as primary form caused by genetic abnormalities and secondary form resulting from other diseases or medications such as diabetes mellitus, hypothyroidism, nephrotic syndrome, estrogen or retinoid treatments and alcohol abuse. Xanthomas are the localized lipid depositions in the skin. It is divided to 4 types as eruptive, tendinous, tuberous, and planar, by anatomical localization of the lesions and mode of development (Park et al., 2005). Eruptive xanthoma, the most common type, appears as crops of discrete yellowish papules and localizes on hands, extensor surfaces and buttocks. Early lesions may have erythematous base and associated pruritus (Henning and Fazio, 2011; Merola

Eruptive xanthomas typically occur in patients with severe hypertriglyceridemia, increased chylomicron and increased very low density lipoprotein (VLDL) cholesterol, most commonly type V hyperlipidemia (Park et al., 2005). Also, eruptive xanthoma may develop due to the secondary hyperlipoproteinemia (Henning and Fazio, 2011; Park et al., 2005). Moreover, familial hyperlipidemia may be exacerbated by factors that may cause secondary hyperlipidemia (Park et al., 2005). The present case had familial hyperlipoproteinemia but the levels of cholesterol and triglyceride had not increased over 1000 mg per dL until he drunk hawthorn vinegar. Because of this, we think that hawthorn vinegar might have exacerbated acute increase in levels of lipids and glucose.

Hawthorn, the genus Crataegus included more than 250 species is believed to have originated from northern temperate regions. The species are widely distributed in western Asia, North America and Europe. The wild Crataegus plants grow naturally in Turkey, mostly in the Aegean, East Mediterranean, Southern Anatolia and Northeast Anatolia. Hawthorn plants have a high morphological diversity, particularly in leaf, flower, and fruit characteristics (Yilmaz et al., 2010).
