Numbers of New Cases and Trends of Cancer 1993-2012: Srinagarind Hospital Based Population, Khon Kaen, North-East Thailand

Kosin Wirasorn¹, Krittika Suwanrungruang², Surapon Wiangnon³, Wiyada Punjaruk⁴*

Abstract

**Background**: Cancer is the most common cause of death in Thailand, where treatment outcomes and prognosis are poor and mortality rates remain high. This study reports new cancer cases and trends of all cancers registered in Srinagarind Hospital from 1993 to 2012 and also provides a picture of the cancer situation in Northeast Thailand. **Materials and Methods**: All new cases of cancer registered in the hospital-based cancer registry at Faculty of Medicine, Srinagarind Hospital, Khon Kaen University during 1993-2012 were included in the study. **Results and Conclusions**: The number of new cancer cases has gradually increased each year during the last 20 years. The three most common cancers at present in males are liver and bile duct cancer, lung cancer and colorectal cancer, respectively. In females, liver and bile duct, breast and thyroid cancers are now the most frequent. Interestingly, the number of cases of both liver and bile duct cancer and colorectal cancer in males noticeably increased during the second decade of the study. Additionally, breast cancer greatly increased in the same decade and lung cancer in females climbed into the top five most common cancers. Thyroid cancer has also risen steadily in the last decade. Trends of common cancers are similar to those throughout Thailand.

Keywords: Numbers of new cases - cancer - Srinagarind Hospital - hospital based cancer registration

Introduction

Cancer is a leading cause of death worldwide in both developed and developing countries, including Thailand (Siegel et al., 2012; Ferlay et al., 2010; Sriplung et al., 2005). In Thailand, the incidence of all cancers and the mortality rate resulting from malignant diseases gradually increase each year. In particular, incidences of colorectal cancer and breast cancer significantly increased during 1989-2000 (Sriplung et al., 2006). Lung cancer, in both males and females, is the most common cancer in many countries (Siegel et al., 2012). However, in Thailand, liver cancer is the most common cancer in males and breast cancer in many parts of the country is the commonest cancer in females (Sriplung et al., 2005), (Public Health Statistic, 2010, reported in Thai language). The number of patients diagnosed with cancer has noticeably increased in Srinagarind Hospital during the last 10 years (unpublished data, reported from Cancer Unit of Srinagarind hospital, 2000-2012). We therefore prepared this overview of all new cancer cases recorded in Srinagarind Hospital during 1993-2012, with an emphasis on changing trends in types of cancer in NE Thailand.

Materials and Methods

**Population and registration procedure**

**Case definitions**: All new cancer cases registered in Srinagarind Hospital between January 1st, 1993 and December 31st, 2012 were included in this study. This study is officially approved by the Khon Kaen University Ethics Committee for Human Research based on the Declaration of Helsinki and the ICH Good Clinical Practice Guidelines with HE571238 of reference number. **Sources of data**: Srinagarind Hospital, Khon Kaen University (a thousand-bed university hospital), Khon Kaen, Thailand, is situated in the center of NE Thailand and accepts all referred cases from other health care centers in the region. Our data were obtained from the Khon Kaen Cancer Registry, which has recorded data of all cancer cases treated in this hospital since 1987. All data were verified, checked for coding duplication and entered into the CANREG software (Version 4, available from http://www.iacr.com.fr/canreg4.htm). The data normally collected from each cancer patient included age, sex, date of birth, date of diagnosis, method of diagnosis, primary site of cancer, extension or metastasis, histology of cancer,
date of last visit, vital status at last follow-up and other necessary information. Deaths were not recorded but these data can be obtained from the civil registration database, if they are required. Only relevant data were presented in this study.

Statistical methods

The data were analysed using Poisson regression to compare the trends in the first decade (1993-2002) and the second decade (2003-2012).

Results

Overall numbers and trends of new cancer cases, 1993-2012

The numbers of new cancer cases recorded between 1993 and 2012 in Srinagarind Hospital are shown in Figure 1. For some analyses, the data were divided into 2 intervals; the first decade (1993-2002) and the second decade (2003-2012). The overall numbers of cancer cases were fairly constant from 1993 to 2005, but has shown an apparently accelerating increase since then. The numbers of male and female patients during the period surveyed were comparable, male patients being slightly more numerous than female. Both genders showed an increase in the last few years, and especially in the period 2010-2012.

Overview of the most common cancers in male and female, 1993-2012

The most common cancers in patients, both male and female, registered in Srinagarind Hospital for the period 1993 to 2012, are shown in Tables 1 and 2, respectively. The order of presentation in the tables is based on the numbers of cases of each type of cancer in the final year of the study. Additionally, data on the five or six most common cancers during 1993-2012 are presented graphically in Figures 2 and 3 for male and female, respectively.

Cancer of the liver and bile ducts was the most common cancer in both males and females (Tables 1 and 2; Figures 2 and 3). In males, this made up over 50% of all cancer cases (Table 1) and has shown a marked increase over the last few years. In females, the number of liver and bile duct cancer cases was approximately half of that in males, despite similar numbers of cancer patients of each gender. In females, cervical cancer was the most common cancer during the first decade of the study (Figure 3) but was subsequently surpassed by cancer of the liver and bile ducts and by breast cancer in the second decade (Table 2 and Figure 3). Nevertheless, in females numbers of cases of cervical cancer almost matched liver and bile duct cancer cases overall, despite very substantial reductions in numbers of cases of the former in recent years.

The second most common cancer in males was lung cancer (Table 1) while it was the sixth most common cancer overall in females (Table 2). The number of new lung cancer cases in males was reasonably constant at approximately 250 cases/year through the 20 year period reviewed (Figure 2) whereas it has gradually increased in females only in the last 10 years and markedly risen especially in the last few years (Figure 3). In 1993, the number of lung cancer cases in females was roughly 50 per year compared to 200/year in 2012. Consequently, lung cancer climbed up into the top five most common cancer in females during the recent 10 years observed. Breast cancer was the second most common cancer in females. Interestingly, the number of breast cancer cases was stable at approximately 200 cases/year during the first 10 years (Figure 3) then increased dramatically up to about 450 cases/year by the end of the second decade (Figure 3).

Colorectal cancer was the third and sixth most common cancer occurring in males and females, respectively (Tables 1 and 2), higher numbers of cases being reported from males (2,275 vs 1,846). The number of cases of colorectal cancer in males was stable at or below 100

Cases per year during the first decade studied but increased considerably during the second decade (Figure 2). Similarly, the number of female patients with colorectal cancer has increased steadily during the last 20 years (Table 2). The four most common cancers in females were thyroid cancer with steadily increasing numbers of cases over the period surveyed. Approximately 70 cases/year were diagnosed in the early 1990s, rising to 300 cases/year during the first decade studied but increased considerably during the second decade (Figure 2). The four most common cancers in females were thyroid cancer with steadily increasing numbers of cases over the period surveyed. Approximately 70 cases/year were diagnosed in the early 1990s, rising to 300 cases/year during the first decade studied but increased considerably during the second decade (Figure 2). **Discussion**

Srinagarind Hospital is a major tertiary health care center for Northeast Thailand, receiving referrals from all over the region and thereby serving a population of around 22 million people. The hospital is served by many subspecialty physicians with expertise on malignancy, hence, most cancer cases in the NE are referred here to receive the proper management. The data reported here therefore likely reflect actual cancer trends within the broad region.

This study reveals that the overall numbers of cancer cases has increased, especially in the seconddecade of the study and the results are consistent with the incidence of cancer elsewhere in Thailand (Sriplung et al., 2005 and Public Health Statistic, 2010, reported in Thai language). The three most common cancers in males in Thailand during 2004-2006 were colorectal cancer, lung cancer and liver and bile duct cancer, respectively (Khuhaprema et al., 2012). Additionally, breast cancer, cervix and uterus cancer and colorectal cancers are the three most common cancers occurring in females in Thailand (Sriplung, et al., 2003; Khuhaprema et al., 2007; 2010; 2012). Thus the results from Srinagarind Hospital during the past 20

DOI:http://dx.doi.org/10.7314/APJCP.2014.15.19.8423
years are quite similar to those of Thailand as a whole. A major point to note is that liver and bile duct cancer was the most commonly seen cancer in female patients studied in Srinagarind Hospital, whereas it occupies sixth position in the country as a whole. The proportion of liver and bile duct cancer recorded in Srinagarind hospital is noticeably higher than that of the other part of Thailand. The Northeast region has a high incidence of *Opisthorchis viverrini* (liver fluke) infection because members of the local population frequently consume uncooked cyprinid fish, which are the intermediate hosts of this parasite (Sripa and Pairojkul, 2008). *Opisthorchiasis* is a significant risk factor for bile duct cancer (Sripa et al., 2011). The apparent increase in numbers of liver and bile duct cancers in the last 10 years is probably due to the increasing numbers of referred cases from primary health care centers, extensive health promotion about causes of cholangiocarcinoma (CCA) leading to increased patient awareness, and improved diagnostic technology. In addition, Srinagarind Hospital is famous for expertise on treatment of CCA and some other cancers, hence attracting patients from all over Thailand.

Since we only report numbers of recorded hospital-based cases, we cannot say whether community incidences of these cancers have changed in the population at large in the period 1993-2012. As mentioned above, numbers of cases reaching Srinagarind Hospital will change according to changes in diagnostic methods and referral patterns, especially if increasing numbers of cases from outside NE Thailand are being referred to Khon Kaen. Changes in screening and early intervention methods might also have influenced the data, as is likely the case for cervical cancer. An effective campaign to promote cervical cancer scanning by Pap smear has been in place in Thailand since 2002 (Kasimpila et al., 2011). In addition, HPV vaccine has been promoted during the last few years in Thailand. These two interventions are expected to reduce the incidence of cervical cancer (Praditsitthikorn et al., 2011) and that is likely reflected in our data.

The increased overall number of cancer cases might be due to demographic factors, such as increasing population size and greater longevity of individuals. It may also reflect an increase in high risk behavior such as unsafe sex leading to HIV or HPV infection, and metabolic syndromes such as diabetes mellitus and obesity (Rattanamongkolgul et al., 2004; Panunphak et al., 2013; Suthipintawong et al., 2011; Aekplakorn et al., 2004).

The increased numbers of lung cancer cases in females, which is similar to worldwide trends (Mathers et al., 2001; Greenlee et al., 2000), might be because of changing life styles leading, for example, to an increase in passive smoking in bars, pubs and night clubs (Kamsa-Ard et al., 2013). Anti-smoking campaigns are strongly promoted in Thailand; however, fewer females than males seem to be responding (Sagerup et al., 2011) and the numbers of new lung cancer cases in females is still gradually rising. In the last 10 years, the number of breast cancer cases in females has noticeably increased. This might result from the increase in obesity, and the adoption of fat-rich Western diets by the Thai population during recent decades (Sangrajrang et al., 2013). Other factors that may play a part include late child bearing, having fewer children and physical inactivity, all associated with increased westernization (Jemal et al., 2010).
