trans geometry.

Recently, Bergman and his coworkers reported an insertion of CO into an Ir=N bond in Cp*Ir=NNBu3 (Cp*=C5(CH3)5), which is the first carbonylation of a terminal imido ligand to give an isocyanate complex. The results of above studies prompted us to investigate the possibility of insertion of CO into Re-nitrene bonds in our compounds. No reactions of compound II or III with CO (up to 6 atm) have been observed.

Kinetics and Mechanism of Aminolysis of Phenyl Benzoates in Acetonitrile

Han Joong Koh, Ho Chan Lee, Hai Whang Lee, and Ikchoon Lee

Department of Chemistry, Inha University, Inchon 462-751, Korea

Received May 31, 1995

The kinetics and mechanism of the reactions of phenyl benzoates with benzylamines and pyrrolidine are investigated in acetonitrile. The variations of ρx (ρx>0) and ρz (ρz<0) with respect to the substituent in the substrate (σp) indicate that the reactions proceed through a tetrahedral intermediate, T2, with its breakdown in the rate determining step. The large magnitudes of ρx, ρy, and ρz as well as the effects of secondary kinetic isotope effects involving deuterated nucleophiles are also in line with the proposed mechanism.

Introduction

The mechanism of ester aminolysis has been extensively studied. The nucleophilic reactions of a series of structurally similar amines with various esters exhibit curved Brønsted-type plots (for βmax(β0)) when the basicity of the leaving group is relatively low. The nonlinear plots have been interpreted in terms of a tetrahedral intermediate, T2, along the reaction path (eq. 1 where X, Y and Z represent substituents in the nucleophile, substrate, and leaving group, respectively) and a change in the rate-limiting step from breakdown to products (k2) of T2 to its formation (k4) as the amine becomes more basic. In contrast to the generally accepted view of the past 20-30 years that the nucleophilic substitution reactions at a carboxyl group involve almost invariably the tetrahedral intermediate, it has been shown recently that some acyl transfer reactions can involve a concerted mechanism. Most of these studies are, however, carried out in protic solvents, typically in aqueous solution. Recent results of aminolysis studies of esters and acyl halides have shown that the similar mecha-
nism involving the tetrahedral intermediate also applies in aprotic solvents like acetonitrile, dioxane etc.

In our developing works of the cross-interaction constants, $\rho_2$ (or $\beta_2$) in eq. 2 where $i, j = X, Y$ or $Z$ in Scheme 1, as a mechanistic tool for organic reactions

$$\log(k_{i1}/k_{i2}) = \rho_{i1} + \rho_{i2} + \rho_{i3}\sigma_{ij}$$

$$\log(k_{i2}/k_{i1}) = \beta_{i1} + \beta_{i2} + \beta_{i3}\rho_{ij}$$

in solution, we arrived at the conclusion that: The signs of $\rho_{XY}>0$ and $\rho_{XZ}<0$ for the stepwise carbonyl addition reactions involving the rate-limiting breakdown of the tetrahedral intermediate, $T^*$, are exactly opposite to those ($\rho_{XY}<0$ and $\rho_{XZ}>0$) for the concerted nucleophilic displacement mechanism.

We now report a study of the aminolysis of phenyl benzoxides by primary amines, benzylamines, and by a secondary amine, pyrrolidine, in acetonitrile solution, eqs. 3 and 4. Our purpose in this study is to apply the mechanistic criteria based on the sign of $\rho_{XY}$ and $\rho_{XZ}$ to the ester aminolysis reactions in aprotic solvent to show general applicability of the criteria.

Results and Discussion

The second-order rate constants, $k_2$, for the reactions of $p$-nitrophenyl benzoates with benzylamines were obtained from $k_{i2}$ and $k_{i1}$ plots with more than four nucleophile concentrations, $[\text{Nu}]$. The general rate law for these reactions is given by eq. 5,

$$k_{obs} = k_2[\text{Nu}]$$

where the rate constant in the absence of amine is zero. The $k_2$ values observed at three temperatures are summarized in Table 1 together with the Hammett ($\rho_2$ and $\rho_1$) and Brönsted constants ($\beta_2$). The $\rho_{XY}$ values determined by subjecting the rate constants, $k_2$, to multiple regression analysis using eq. 2a with $i, j = X, Y$ are also included in the Table. We note that the magnitude of $\rho_{XY}$ values is relatively low ($\rho_{XY} = -0.36$ to $-0.76$ at 35.0 °C), especially for $Y = p$-NO$_2$. In terms of the mechanism involving rate-limiting breakdown of a zwitterionic tetrahedral intermediate, $T^*$, in eq. 1 where $\text{X} = \text{NC}_6\text{H}_4\text{CH}_3\text{NH}_2$, $\text{RY} = \text{CH}_3\text{CH}_2\text{Y}$ and $\text{LZ} = \text{OC}_2\text{H}_5\text{NO}_2$ for the reactions in Table 1, the trend of change in $\rho_2$ with substituent $Y$ is reasonable; electron-withdrawing

$^{a}$If we allow for the fall off factor of 2.8 for a non-conjugating intervening group, CH$_3$ in benzylamine (relative to aniline), $\rho_2$ ranges ca. 1.0-2.1, which is still relatively small for a reaction involving an addition intermediate formation in protic solvents ($|\rho_2| \geq 3.0$).
Aminolysis of Phenyl Benzoates

![Energy diagram](image)

**Figure 1.** Schematic energy profile along the reaction coordinate for the partitioning of $T^*$ with $E(TS1)=E(TS2)$ required when $\delta(k_{-d}/k_1)>0$.

drawal from the nonleaving group ($\delta p_X>0$ in RX, Table 1) favors amine expulsion ($\delta p_X>0$ or $\delta p_X<0$, Table 1) from $T^*$ (TS1) relative to $p$-nitrophenoxide release (TS2), i.e., $k_{-d}/k_3$ in eq. 1 increases as RX becomes more electron withdrawing, leading to a lower barrier for TS1 with $k_3$ (TS2) as the rate-determining step. The relatively smaller magnitude of $\rho_X(k_{-d})$ found could be due to a less polar solvent used (MeCN) in this work, which should also increase $k_{-d}$ and have little or no effect on $k_{-d}$ (vide infra).

Applying the steady-state treatment to $T^*$ gives $k_{2/3}=k_2/k_3$ ($k_{-s}+k_p$) where $K=k_{2/3}$ is the macroscopic rate constant defined in eq. 5. For the rate-limiting breakdown of $T^*$, $k_2=Kk_{-d}$ where $K=k_{-d}/k_{-s}$.

![Chemical structures](image)

**TS 1 (for $k_1$ in eq 1)**

**TS 2 (for $k_3$ in eq 1)**

The relatively smaller magnitude of $\rho_X$ (and also $\beta_X$) in a less polar solvent (MeCN versus aqueous solution) and for a stronger electron-withdrawing Y substituent in RX, for which $k_{-d}/k_3$ increases to a greater value ($\delta(k_{-d}/k_3)>0$), can be rationalized with these relations, $k_2=Kk_3$ and $K=k_3/k_{-d}$.

The observed $\rho_X$ value listed in Table 1 is in fact a complex quantity.

$$\rho_X^{(obs)} = -\frac{\partial \log K}{\partial \sigma_X} = \frac{\partial \log K}{\partial \sigma_X} + \frac{\partial \log K}{\partial \sigma_Y}$$

$$= \frac{\partial \log K}{\partial \sigma_X} + \frac{\partial \log K}{\partial \sigma_Y} - \frac{\partial \log K}{\partial \sigma_Y}$$

$$= \rho_X(k_2) - \rho_X(k_{-d}) + \rho_X(k_3)$$

$$= (-) - (+) + (-)$$

Consideration of the effect of $\sigma_Y$ on the three rate constants leads to $\rho_Y(k_2)<0$, $\rho_Y(k_{-d})=0$ and $\rho_X(k_3)<0$. The term will be relatively small, because this term reflects the effect of substituent in the amine ($\sigma_X$) on the rate of leaving group expulsion, $k_3$, from the intermediate, $T^*$ (a secondary effect). Eq. 6 asserts that the observed $\rho_X$ values in the rate-limiting breakdown of $T^*$ should be large negative in general since all three terms in eq. 6 are contributing additively to the negative $\rho_X^{(obs)}$ value. When, however, $k_{-d}/k_3$ increases, especially in a less polar solvent, the greater rate increase in $k_{-d}$ relative to $k_3$ results in a greater decrease in the magnitude of $\rho_X(k_{-d})$ relative to $\rho_X(k_3)$; this is expected from the reactivity-selectivity relations found in Table 1, i.e., the rate increase is always accompanied by a decrease in the selectivity, $\rho_X$ and $\beta_X$. The relatively large decrease in $\rho_X$ ($k_{-d}$) with very little effect on $\rho_X(k_3)$ should result in a smaller negative $\rho_X^{(obs)}$ value ($\delta p_X>0$), as we have found in Table 1, for the less polar solvent, MeCN, as well as for RX with the more electron-withdrawing substituent ($\delta p_X>0$); this latter is really a necessary condition (a positive $\rho_X$ value, $\rho_X=-\partial \rho_X/\partial p_X>0$) for the rate-limiting breakdown of $T^*$. Similar argument leads to the generally large $\beta_X(k_{-d})$ values for the reactions proceeding by the rate-limiting breakdown of $T^*$, but the magnitude decreases to smaller $\beta_X(k_{-d})$ values in a less polar solvent (MeCN) and for the reactions involving with a stronger electron withdrawing Y substituent, when we differentiate $\log k$ with respect to $\rho_Y(X)$ instead of $\sigma_Y$ in eq. 6 (Table 1).

For these reactions, the sign of $\rho_X$ was found to be positive (Table 1). Thus

$$\rho_X = \frac{\partial \log K}{\partial \sigma_X} = \frac{\partial \log K}{\partial \sigma_Y} + \frac{\partial \log K}{\partial \sigma_Y} > 0$$

Since in the rate-determining step, $k_3$, the change in the intensity of interaction between substituents X and Y is insignificant, i.e., $\partial \log K/\partial \sigma_X = 0$, eq. 7 can be simplified to eq. 8. This shows that the $\rho_X$ value calculated with $k_2$

$$\rho_X = \frac{\partial \log K}{\partial \sigma_Y} = \rho_X$$

corresponds to the $\rho_X$ value calculated with $K$, $\rho_X^{(obs)}$. In the equilibrium step, i.e., for the change involved in the two separated reactants forming an intermediate (a covalent complex), the change in the intensity of interaction is equal to that within a covalent-bonded complex and hence should be very large; for the separated reactants the interaction between X and Y is zero, $\rho_X^{(obs)}=0$, and $\rho_X^{(obs)}$ becomes equal to that within a covalent-bonded system, $\rho_X^{(obs)}$.

$$\rho_X = \rho_X^{(obs)}$$

This is why the $\rho_X$ values are relatively large in Table 1 (where compared to the $\rho_X^{(obs)}$ values obtained for the reactions with anilines the $\rho_X$ values in Table 1 should become larger ($\rho_X \geq 1.0$) when the fall-off factor of $\alpha_X. 2.8$ for the nucleophile, benzylamine vs aniline, is taken into consideration).$^6$ Again the positive $\rho_X$ value ($\rho_X$ in Table 1) is consistent with the rate-limiting breakdown of $T^*$. Jenkins et al.$^{(1b)}$ and Castro et al.$^{(1a,6)}$, have shown that in the partitioning of the tetrahedral intermediate, $T^*$, in eq. 1 leaving group expulsion is favored, or conversely amine expulsion is disfavored ($\delta p_X<0$), from $T^*$ as the group that remains behind (RY) becomes more electron donating ($\delta p_X<0$), leading to $\partial \rho_X/\partial \sigma_Y = \rho_X>0$. Reference to Table 1 reveals that the variation of $\rho_X$ with respect to $\sigma_Y$ is in the right direction.

$^6$ Available experimental results indicated that in the nucleophilic substitution reactions of carbonyl compounds, the reactivity-selectivity principle (RSP), i.e., a greater reactivity leading to a smaller selectivity, holds in general. In addition to the results in this work, references 1i, 2a, 3, 7 and the following papers support this contention: Lee, I.; Shim, C. S.; Lee, H. W. J. Chem. Res., 1992 (S), 90. Castro, E. A.; Salas, M. Santos, J. G. J. Org. Chem., 1994, 59, 30.

*Standard deviation. †Standard error."}

For a rate-limiting breakdown of $T^*$, the $\beta_{S}(\beta_{emp})$ value has been found to be large, $\beta_{S} \approx 1.0$, for the reactions in protic solvents (vide supra). Although the $\beta_{S}$ values in Table 1 are low ($\beta_{S}=0.36-0.73$ at 35.0 °C obtained by $pK_a$ values in water not in MeCN) the direct comparison of the $\beta_{S}$ values with those reported in the aqueous solution may not be justified, since the solvent effect and especially the use of $pK_a$ in water invalidate such a comparison.

The magnitude of $\rho_T$ in Table 1 (1.04-1.26 at 35.0 °C) is similar to those of Menger et al., for the reactions of phenyl benzoates with pyrrolidine in acetonitrile at 25.0 °C ($\rho_T=1.01-1.4$).

It is notable that the temperature coefficient of both $\rho_T$ and $\rho_XY$ are ca. 6% decrease per 10° rise. This decrease in the size of $\rho_XY$ is an indication that the degree of bond-making decreases i.e., becomes looser as the temperature is raised.

The secondary kinetic isotope effects, $k_{d}/k_{p}$, involving deuterated benzylamine nucleophiles in Table 2 are shown in Table 2. The $k_{d}/k_{p}$ values are all near unity ranging 1.03 to 1.07.

The magnitude of $k_{d}/k_{p}$ is again similar to that reported by Menger et al. (0.53-1.09) for the reactions of $p$-nitrophenyl acetate with deuterated primary and secondary amines in acetonitrile and chlorobenzene at 25.0 °C. Although $k_{d}/k_{p}$ in Table 2 differs little between different substituents X and Y, there is a distinctive trend of change: the $k_{d}/k_{p}$ values are greater for electron-donating Y ($\text{XC}_6\text{H}_4\text{CH}_2\text{ND}_2$) and electron-withdrawing X (X=p-Cl). This is consistent with the rate-determining step, since a stronger electron-donating Y ($\delta_{D}<0$) and an electron-withdrawing X ($\delta_{D}>0$) in the intermediate, $T^*$, should lead to a greater degree of C-O bond cleavage in the TS ($\delta_{D}>0$); these changes are in line with the signs of $\rho_XY=\partial \rho_X/\partial \delta_Y$ ($<0$) and $\rho_{XY}=\partial \rho_X/\partial \delta_Y$ ($>0$). A greater degree of bond cleavage should lead to a greater $\beta$-secondary deuterium isotope effect due to a greater $\sigma_{NO}$ hyperconjugation toward the empty p orbital forming as the C-O bond cleavage takes place.

The relatively low activation parameters, $\Delta H^*$ and $\Delta S^*$, in Table 3 are also in accord with the mechanism proposed. Castro et al. (1986), have shown that for the rate-limiting $k_2$ step, relatively low $\Delta H^*$ and $\Delta S^*$ (large negative) are values one expected.

The $k_2$ and $k_3$ values from eq. 5 for the reactions of $p$-nitrophenyl Y-benzoates with pyrrolidine nucleophile are collected in Table 4.

We have varied the pyrrolidine concentrations up to 0.5 mole-dm$^{-3}$ and the $k_{obs}/[\text{Nu}]$ plots versus [Nu] gave straight lines with intercept, $k_2$, and slope, $k_3$, as required from eq. 5 for the relatively weak nucleofuge, $Z=\text{H}$, $p$-Cl.

and p-CN. For a stronger nucleofuge, Z = m-NO$_2$ and p-NO$_2$, however, no detectable k$_2$ steps was obtained.

We note in Table 4 that the p$_2$ values for both k$_1$ and k$_2$ steps are very large as reported by Menger et al.$^3$ for the reactions of Z-phenyl acetates. Strikingly, changes in p$_1$ with substituent in the leaving group (Z) is large for both steps and the cross-interaction constants, p$_{12}$, are relatively large negative. An electron-withdrawing substituent in the leaving group (ðð$_2$>0) should shift the equilibrium, eq. 1, to the right, since the anion product, LZ$^-$, is stabilized. As a result, the second barrier (TS2) is lowered and accelerates the second step, k$_2$, leading to a larger p$_2$ value. The use of the relation k$_2$ = k$_1$ k$_2$ should lead to a similar three term equation with eq. 6 and the three component p$_2$ values will augment to give a large observed p$_2$ value (Table 4). The effect of substituent, Z, on the aminolysis rates should be large, particularly since the anionic oxygen is poorly solvated in acetonitrile. Thus the unusually large p values observed in Table 4 support the mechanism in which breakdown of T$^+$ is rate-limiting.

The negative sign of p$_{12}$ is in accord with the rate-limiting breakdown of T$^+$. It requires that a stronger electron-withdrawing substituent in RY (i.e., 3(30)<0) should lead to a smaller p$_2$ value (3(30)<0) i.e., 3(30) = 3(30)3(30)<0. This is again consistent with the experimental results by Jencks et al.$^1$ and also by Castro et al.$^2$ that in the partitioning of T$^+$ amine expulsion is favored, or conversely leaving group expulsion is disfavored (3(30)<0, as the group that remains behind (RY) becomes more electron withdrawing (330<0) leading to 3(30)/330 = 3(30)<0; thus our results in both Tables 1 and 4 are consistent with their experimental conclusions regarding the effect of the nonleaving group in the mechanism involving rate-limiting breakdown of T$^+$, 3(30) = 3(30)/330>0, 3(30) = 3(30)/330<0.

In order to investigate the effects of primary and secondary amine nucleophiles on the Bronsted $k_2$ value, we have determined k$_2$ values for the reactions of p-nitrophenyl Y-benzoates with three secondary amines as shown in Table 5. The plot of log $k_2$ (Table 5) versus $p_K_a$ is presented in Figure 2.

The overall linearity is poor (r = 0.867) with $k_2 =$ 1.28. The large scatter probably results from the different kind of amines as well as from the use of $p_K_a$ in water, not the $p_K_a$ value in acetonitrile used in this work. However the large $p_X$ value with a poor linearity is quite similar to those reported for the similar reactions in aprotic solvent; for p-nitrophenyl 3,5-dinitrobenzoate in acetonitrile a plot of log $k_2$ versus $p_K_a$ (water) for the primary amines gave a slope of ca. 2.5, while for benzoyl fluoride in dioxane with primary amines gave a slope of 1.0.

Conclusions

The variations of $p_X$ (3(30)>0) and $p_2$ (3(30)<0) with changes in the substituent in the substrate (3(30)) are consistent with the experimentally observed trends in the literature for the rate-limiting breakdown of the tetrahedral intermediate. The relatively greater magnitudes of 3(30), 3(30), and 3(30) and the secondary kinetic isotope effects involving deuterated nucleophiles are also in line with the proposed mechanism.

Experimental

Materials. Acetonitrile was distilled twice over phosphorus pentoxide and again over anhydrous potassium carbonate using a 30 cm vigreux column. Preparation of deuterated benzylamines was described previously.$^3$ Since the content of deuterium in the deuterated benzylamines is greater than 98% determined from the analysis of NMR spectra, no corrections were made to the kinetic isotope effect. Phenyl benzoates were prepared by the reactions of equimolar amounts of the substituted benzoyl chlorides with substituted phenol in dry pyridine. The reaction mixtures were heated, allowed to stand for several hours, and poured into five to tenfold excess of cool water. Final products were obtained by the filtration and recrystallized twice using acetone, methanol, as a mixture of the two solvents.$^3$

Kinetic procedures. Rates were measured conducti-
metrically at 35.0, 45.0 and 55.0 °C in acetonitrile. The conductivity bridge used in this work was a self-made computer interface automatic A/D converter conductivity bridge. Pseudo-first order rate constants, kobs, were determined by the Guggenheim method with a large excess of amine; [phenyl benzoate]=5.0×10⁻⁴ mol dm⁻³ and [amine]=0.03-0.40 mol dm⁻³. Aminolyses of phenyl benzoates in aprotic solvent under pseudo-first order conditions obey a two-term rate law, eq. (5). The rate constants, k₁ and k₂, were determined from the intercepts and the slopes of the plot of kobs/[amine] is [amine], respectively. In a few cases the k₃ term was not observed. The k₂ and k₃ values in Tables 1 and 4 are the averages of more than triplicate runs and were reproducible to within ±3%.

**Products analysis.** p-Nitrophenyl p-methylenzoate was reacted with excess p-methyl benzylamine with stirring for more than 15 half-lives at 35.0 °C in acetonitrile, and the products were isolated by evaporating the solvent under reduced pressure. The TLC analysis of the product mixture gave three spots (silica gel, glass plate, 10% ethyl acetate/n-hexane).

**Rf values.** 0.35 (p-C₆H₅C₆H₂CONHCH₂C₆H₄-p-CH₃), 0.65 (p-C₆H₅C₆H₂CH₂NH₂), 0.02 (p-C₆H₅C₆H₂CH₂NH₃⁺OC₆H₅-p-NO₂).

The product mixture was treated with column chromatography (silica gel, 10% ethyl acetate/n-hexane). Analysis of the product, p-C₆H₅C₆H₂CONHCH₂C₆H₄-p-CH₃, gave the following results.

p-C₆H₅C₆H₂CONHCH₂C₆H₄-p-CH₃: mp 130-131 °C; IR (KBr), 3300 (NH), 1660 (C=O); NMR (CDCl₃), 7.1-7.6 (8H, m, phenyl), 6.5 (1H, s, NH), 4.6 (2H, d, CH₂), 2.4 (3H, s, CH₃ (benzylic)), 2.2 (3H, s, CH₃ (benzylic)).
