Key Words: Critical micelle concentration (CMC), Cyclic voltammetry, Compounds having pyridine

Electrochemical behavior of CMC in sodium dodecyl sulfate (SDS)-tris(2,2'-bipyridyl)ruthenium(II) (Ru(bpy))\(^{2+}\) solution is reported using a cyclic voltammetry (CV). Discussion of SDS-Ru(bpy)\(^{2+}\) solution is restricted to the regions slightly below and above the CMC.

Kaifer and Bard suggested that detection of the CMC of SDS for methyl viologen is possible through the changes observed in the shape of cyclic voltamograms. This work was originated from doing experiment for enhancement of electrogenerated chemiluminescence intensity in the Ru(bpy)\(^{2+}\) solution with surfactants. Until recently, most applications of aqueous micelles were restricted to regions extending slightly below and above the CMC. Because, the interesting effects are being discovered at surfactant concentrations much below and above the critical point.

Although various techniques of electrical conductance, turbidity, osmotic pressure, magnetic resonance, solubilization, light scattering intensity,\(^8,9,10\) surface tension,\(^8,11,12\) and fluorescence quenching\(^13\) to measure the CMC have been utilized, a determination of the CMC by the CV has been received little attention.\(^1,14\) And so, in this work the method of determining the CMC for compounds having pyridine is explained, and a variation of the microenvironments of SDS-Ru(bpy)\(^{2+}\) interactions in the vicinity of the CMC is discussed by using the model proposed by Brajter-Toth et al.\(^15,16\)

Experimental Section

SDS, Ru(bpy)\(^{2+}\), and H\(_2\)SO\(_4\) were obtained from Aldrich, Aldrich, and Wako chemicals, respectively, and used without further purification. Doubly distilled water was used to prepare all solutions. Glassy carbon disk (Bioanalytical Systems, West Lafayette, in USA) with a geometric area of 0.0788 cm\(^2\) was used as a working electrode. It was polished with 0.05 \(\mu m\) \(\gamma\)-alumina/water slurry on a felt surface and then exposed to ultrasonic cleaning about 2 min. A saturated calomel electrode (SCE) and a platinum mesh were used as a reference electrode and an auxiliary electrode, respectively. All electrochemical experiments were performed under a purified nitrogen atmosphere at 25 ± 0.2 °C.

Results and Discussion

Cyclic voltammograms of 1.0 mM Ru(bpy)\(^{2+}\) in 100 mM H\(_2\)SO\(_4\) solution with and without SDS at 25.0 ± 0.2 °C. Scan rate = 100 mV/s except for [SDS] = 4.5 mM (20 mV/s). (a) [SDS] = 0 mM; (b) [SDS] = 3.5 mM; (c) [SDS] = 4.5 mM; (d) [SDS] = 7.0 mM.

Table 1. Electrochemical Data for 1.0 mM Ru(bpy)\(^{2+}\) in 100 mM H\(_2\)SO\(_4\) with and without SDS at 25.0 ± 0.2 °C. Scan rate = 100 mV/s

H\(_2\)SO\(_4\) solution with and without SDS are shown in Figure 1(a, b, and d) at scan rate = 100 mV/sec. Data for the redox waves of Ru(bpy)\(^{2+/3+}\) are shown with increasing the concentration of SDS in Table 1.

In the absence of SDS (Figure 1(a)), the sharp peaks in the region A and the peaks in B are not shown. But in the presence of SDS (Figure 1(b-d)), maybe, it seems that those
in the region A and these in B are appeared due to Eq. (1):

\[
\text{Ru(bpy)}_{3}^{2+} + 2 \text{DS}^{-} (\text{dodecyl sulfate anion}) \rightarrow \text{Ru(bpy)}_{3}^{2+}(\text{DS})_2
\]  

At scan rate = 100 mV/sec, those peaks in the region A are appeared approximately in 2.5 mM SDS, reached the maximum in 5.0 mM, and disappeared above 9.0 mM. These in B are perceived as only trace by the eye through moving of the recorder’s pen during the experiment. But these are observed outstandingly at scan rate = 20 mV/sec (Figure 1(c)). That is, at scan rate = 20 mV/sec these are appeared about in 3.5 mM SDS and disappeared above 6.0 mM. The separations between that in the region A and this B potentials are 25-35 mV. Judging from this, it seems that the electrode response is related to two-electrons reaction via Eq. (1).

In the absence of SDS (Figure 1(a) and Table 1), the oxidation of Ru(bpy)\(_{3}^{2+}\) to Ru(bpy)\(_{3}^{3+}\) takes place at \(E_{pa}\) of 1047 mV vs. SCE and reduction of Ru(bpy)\(_{3}^{3+}\) occurs at 984 mV upon scan reversal. The formal potential \(E_{1/2}\) taken as the average of \(E_{pa}\) and \(E_{pc}\) is 1015 mV. From values of the separation between the anodic and the cathodic peak potentials (\(\Delta E_p\)), and the anodic (\(i_{pa}\))/cathodic peak current (\(i_{pc}\)), it can be considered that the redox couple is electrochemically reversible.

In the presence of SDS, \(E_{pa}\) of Ru(bpy)\(_{3}^{2+}\) shifts to positive direction compared to the SDS free case except 2.5 mM SDS. But at 2.5 mM SDS, it seems that shifting of \(E_{pa}\) to negative direction is due to dynamic environment by forming monomers to micelles. Also, \(\Delta E_p\) shows a special phenomenon as [SDS] increases. It decreases up to 3.0 mM SDS and increases above the concentration.

In order to see the relation between \(\Delta E_p\) and a CMC, \(\Delta E_p\) vs. -log[SDS] for the redox couples were plotted in Figure 2. The concentration at the intersection of two lines in Figure 2 is 3.04 mM, this concentration can be determined as the CMC, which (relative error: below 1.5%) is very near a CMC measured by surface tensiometry (3.00 mM SDS, Figure 3).

As mentioned above, the CMC for SDS solution of Ru(bpy)\(_{3}^{2+}\) exists in the vicinity of a minimal value of \(\Delta E_p\). As [SDS] increases up to the CMC, the width of the double layer (i.e., distance to the glassy carbon electrode surface) is narrowed by arranging dodecyl sulfate anionic monomers (\(\text{DS}^-\)) around the electrode, which speeds up the electron transfer.\(^{13,14}\) As [SDS] increases above the CMC, micelles are formed gradually.\(^{18}\) The increase in the number of micelles causes the width of the double layer to increase, which makes the electron transfer slower (i.e. a increase on \(\Delta E_p\)).\(^{15,16}\)

\(i_{pa}\) decreases up to 2.5 mM SDS because of the increase of the electrode surface screening with the increasing in the number of monomers, but increases at 3.0-5.0 mM SDS range above that concentration (see Table 1). This is due to the decrease of the electrode surface screening, because monomers around the electrode become dynamic to form micelles. When [SDS] is reached at 6 mM, \(i_{pa}\) decreases due to the decrease in the number of Ru(bpy)\(_{3}^{2+}\) species per

micelles.\(^\text{18}\)

The CMCs of compounds having pyridine-SDS are listed in Table 2. In addition, in the presence of the other anionic surfactant sodium dodecyl benzene sulfite (SBS), CMC of 1.0 mM tris(1,10-phenanthroline)iron(II) was measured by CV (4.00 mM SBS).\(^\text{22}\) But the addition of both cationic (hexadecyltrimethylammonium bromide) and nonionic (triton X-100; igepal DM-970) surfactants instead of SDS and SBS causes no significant shift in the cyclic voltammetric peak potentials for compounds having pyridine mentioned in Table 2. This invariance of peak potential indicates the absence of interactions between the compound having pyridine and surfactant in each of cationic and nonionic micellar systems.

In the presence of anionic surfactant, therefore, it should be given as a conclusion that CMC of compounds having pyridine can be measured by the intersection of two lines on the $\Delta E_p$ vs. -log[anionic surfactant].
