Key Words: Si(111), Viologen, Electrochemistry, ATR-FTIR, Oxygen

Since Linford and Chidsey demonstrated that pyrolysis of neat diacyl peroxides in the presence of hydrogen-terminated single crystalline silicon led to the formation of a densely-packed organic monolayer covalently bonded to the silicon surface,1,2 studies on the construction of organic monolayers on silicon surfaces has expanded to develop chemical protection strategies for Si surfaces3-5 and to form metal-organic layer-Si junctions for device applications in nanoelectronics.6-8 In this work, we wish to report that silicon surface was functionalized by an organic monolayer with viologen, which was effective for the reduction of molecular oxygen at the silicon surface. We have previously reported electrochemistry of viologens physically as well as chemically self-assembled on electrode surfaces9,10 and chemical modification of light-emitting silicon materials. 11 Masuda and Uosaki’s recent letter12 prompted the present work but a more versatile functional viologen with carboxyl group was immobilized via direct C-Si bond formation at the silicon surface in our case and we present the experimental evidences of viologen-containing organic monolayer formed covalently at Si(111) surfaces by ATR-FTIR and voltammetry.

The parallelogram ATR prism was prepared from phosphorous doped n-type Si(111) wafers (1.0-10 Ωcm), which were polished on both sides for the ATR-FTIR measurements as before.13 Acetone and DI water were used for rinsing Si(111) samples in sonication and piranha solution was used for making oxide layer on silicon surfaces. To obtain a hydrogen-terminated Si(111) surface, the ATR prism was immersed in a 40% NH4F solution and dried in a flowing nitrogen gas. The sample was then thermally treated with 4-vinylbenzyl chloride (4-VBC) and 4-propylcarboxylic-4'-bipyridine, which was prepared from 4,4'-bipyridine and bromopropionic acid, to produce Si-4-vinylbenzyl-1-(2-carboxylethyl)-4,4'-bipyridium (Si-4-VB-VCOOH).

ATR-FTIR measurements were performed using a Bio-Rad Excaliber™ spectrometer equipped with HgCdTe (MCT) detector and home-made sample holder. Ar gas was continuously introduced into the FTIR chamber. The ATR-FTIR spectra were recorded with p- and s-polarization for an oxidized Si(111) surface as a background. Electrochemical experiments were carried out using an EG&G 283A potentiostat in a three electrode electrochemical cell. A Ag/AgCl electrode, a Pt wire, and the Si(111) substrates were used as a reference, a counter, and a working electrode, respectively. The electrolyte solution used was 0.1 M KCl aqueous solution. All the potential was quoted against Ag/AgCl. The preparation sequence of the viologen-containing organic monolayer is shown in Scheme 1.

Figure 1 compares the FTIR spectra of the (a) H-Si(111), (b) 4-VBC-Si(111), and (c) Si-4-VB-VCOOH substrates. Two peaks commonly seen around 2920 cm$^{-1}$ and 2850 cm$^{-1}$ in both (b) and (c) were assigned to the asymmetric and the symmetric CH$_2$ stretching, respectively.1,2,14 The CH$_2$ bending scissors were found around 1470 cm$^{-1}$ as the C=O stretching around 1650 cm$^{-1}$. A broad peak above 3200 cm$^{-1}$ was assigned to OH stretching. The peaks of CH stretching vibrations of the benzene ring were observed between 3000 cm$^{-1}$ and 3100 cm$^{-1}$. As the hydrogen-terminated Si(111) was reacted with 4-vinylbenzyl chloride, a sharp Si-H peak at 2108 cm$^{-1}$ disappeared and new peaks were found around 3040 cm$^{-1}$, 2920 cm$^{-1}$, 2850 cm$^{-1}$ and 1470 cm$^{-1}$, indicating that 4-VBC was successfully immobilized at Si(111) surface via C-Si covalent bond. When Si(111)-4-VBC substrate was further treated with 4-propylcarboxylic-4'-bipyridine, additional peaks were observed around 1650 cm$^{-1}$ for C=O stretching and above 3200 cm$^{-1}$ for O-H stretching, suggesting that covalent binding of 4-propylcarboxylic-4'-bipyridine was achieved at the Cl position of 4-VBC-Si(111). Although it has been previously noted that the O-H stretch, which had disappeared in the hydrogen-terminated Si surface, largely returns when straight alkyl monolayer was formed at Si(111) surface,4 no similar spectral features were
seen in the present work. Although the OH or oxide was discussed to be formed based on the difference in the nearest-neighbor distance between silicon atoms on the Si(111) surface (3.84 Å) and alkyl chains (diameter 4.6 Å),1 the formation of OH or oxide at silicon surface may occur depending on the degree of packing of monolayer formed. We note that it was recently reported that the initial electronic properties and structure of the interface were found to be long-lasting only when the monolayer surface coverage was greater than 0.42, leaving intermolecular channels narrower that 2.82 Å, the diameter of water.4 We believe that we formed such a high-quality 4-VBC monolayer that OH stretching was not seen in Figure 1B.

Figure 2 shows cyclic voltammograms of 4-VBC-Si(111) electrode (a), and the first redox process of viologen (2+/+) at Si-4-VB-VCOOH substrates. ATR-FTIR spectra of (a) H-Si(111), (b) 4-VBC-Si(111), and (c) Si-4-VB-VCOOH substrates.

Figure 2. Cyclic voltammograms of 4-VBC-Si(111) electrode under argon atmosphere (a), and the first redox process of viologen (2+/+) at Si-4-VB-VCOOH in the absence (b) and presence (c) of molecular oxygen in 0.1 M potassium chloride electrolyte solution. Scan rate; 10 mV/S.

of oxygen. These would not be possible unless the bimolecular reaction rate between the reduced viologen bound at the silicon surface and oxygen in solution was extremely fast as was the case with other electrodes.5 The chemically modified silicon electrode may be profitably usable for oxygen sensing. In addition, the carboxyl group at the end of the functionalized viologen on silicon surface can be further derivatized with –NH2 group, for example, in biological molecular system. Work is in progress toward this direction.
