Key Words: Peptide nucleic acids, GNA

In the research of the chemical etiology of nucleic acid structure, the studies from Eschenmoser group\(^1\) and Nielsen group\(^2\) have demonstrated that the Watson-Crick base pairing can be supported by various backbone derivatives. Inspired by the groundbreaking results, other researchers have devoted their attention to finding artificial nucleic acids that can form duplexes, in which both synthetic accessibility and new characteristics for potential therapeutic (or diagnostic) use are desirable aims.\(^3\) In this context, GNA (glycol nucleic acid, Figure 1A) is a promising artificial nucleic acid because it is structurally very simple with a high atom economy and thermal stability of γ\(^3\)T. In contrast to the case in PNA, Figure 1B), in which the phosphate backbone of GNA is replaced by neutral amides, expecting that γ\(^3\)T would have both binding characteristics of GNA and aegPNA (Figure 1B).

Despite of its acyclic and negatively charged phosphate backbone, GNA shows exceptional duplex stability compared to that of DNA.\(^5\) However, the direct use of GNA for biological applications would be hampered by drawbacks such as chemical instability, promiscuous serum binding, and poor cellular uptake. In order to make GNA more practically applicable, we designed a peptide version of GNA (named γ\(^3\)PNA, Figure 1C), in which the phosphate backbone of GNA was replaced by neutral amides, expecting that γ\(^3\)PNA would have both binding characteristics of GNA and aegPNA (Figure 1B).

γ\(^3\)PNA is a chiral peptide nucleic acid composed of γ\(^3\)X monomers (X = A, T, G, and C), which are γ\(^3\)-amino acids attached to the corresponding nucleic acid bases. Previous study from our group has demonstrated that incorporation of a few γ\(^3\)T into the aegPNA backbone (a chimeric PNA) can induce a preorganized helical propensity, by which the parent aegPNA was endowed with an improved binding preference to a target RNA.\(^6\) This initial result has encouraged us to investigate the possibility of self-duplex formation of γ\(^3\)PNA. Herein we report the synthetic methods for the preparation of monomers with other nucleobases (A, C, and G) as well as the thermal stability of γ\(^3\)PNA duplex.

Given the protocol for the synthesis of γ\(^3\)T, we were able to synthesize other monomers (γ\(^3\)A, γ\(^3\)C, and γ\(^3\)G) with high enantiomeric purities. In contrast to the case in γ\(^3\)T, they have nucleophilic exocyclic amino groups on the nucleobases that should be protected for the solid-phase peptide synthesis by Fmoc chemistry. After screening of acid-labile protection groups (such as Bhoc, Boc, and Mmt), we found that the best chemical yield were obtained with Mmt for γ\(^3\)C and γ\(^3\)G, Boc for γ\(^3\)A, respectively. In addition, the order of reactions at the initial steps turned out to be important for efficient synthesis. For example, in case of γ\(^3\)C, the protection of the amino groups should be prior to the substitution reaction, whereas the other route worked better for the purine monomers (γ\(^3\)A and γ\(^3\)G).

The detailed synthetic procedures are summarized in Scheme 1. The common intermediate bromide 1 was easily prepared from (5)-epichlorohydrin (\(>99\)%ee) in three steps (34% overall yield).\(^6\)\(^7\) For the synthesis of γ\(^3\)A, the bromide 1 was reacted with unprotected adenine base in the presence of sodium hydride in DMF for 48 hr at room temperature. After completion of the substitution reaction, the crude adduct was treated with excess amount of Boc anhydride, which unexpectedly resulted in bis-Boc protected product 3 in 61% overall yield. We fortunately found that only one Boc-group could be cleaved during the following ester hydrolysis to give the desired mono-Boc acid 4 in 86% yield. Subsequent reduction of azide followed by Fmoc protection provided γ\(^3\)A in 44% overall yield (Scheme 1a).

For γ\(^3\)G, the bromide 1 was treated with unprotected 2-amino-6-chloropurine in the presence of K\(_2\)CO\(_3\) to get 6 in 83% yield. Mmt protection of 6 provided N\(^2\)-Mmt-protected 7 in 90% yield. The transformation of chloride to carbonyl group and ester hydrolysis occurred simultaneously under the reflux condition with 10% aqueous NaOH, which gave 8 in 90% yield. The azide reduction of 8 followed by Fmoc protection furnished γ\(^3\)G in 60% yield (Scheme 1b). In the case of γ\(^3\)C, cytosine was reacted with Mmt-Cl to prepare N\(^4\)-Mmt-cytosine, which was reacted with 1 to give 10 in good yield (90%). Further sequential manipulation gave the desired

\(^{†}\)This paper is dedicated to Professor Eun Lee on the occasion of his honourable retirement.

Figure 1. Structural relationship among GNA (A), aegPNA (B), and γ\(^3\)PNA(C); Base = T, A, C, or G.
To improve water solubility, a single and mixture (Figure 2a), supporting that our delight, we observed a typical sigmoid curve for the thermal stability of the analogous DNA duplex (4). The thermal stability of PNAs can form a stable duplex, we performed a sodium phosphate buffer (10 mM, pH 7.0) solution of DIC and HOBt in DMF was used as coupling reagent and 20% piperidine in DMF was used for the deprotection of Fmoc group. The resulting γPNAs were cleaved from the resin with TFA. The crude oligomers were purified by reverse-phase HPLC, and confirmed by MALDI-TOF.

To see if the γPNAs can form a stable duplex, we performed temperature-dependent UV-melting experiment at 260 nm to measure the \( T_m \) value of a 1:1 mixture of P1 and P2. To our delight, we observed a typical sigmoid curve for the mixture (Figure 2a), supporting that γPNA forms a duplex through Watson-Crick base pairing. The thermal stability of the γPNA duplex P1:2 (\( T_m = 36 \) °C, measured) exceeds the stability of the analogous DNA duplex (\( T_m = 29 \) °C, calculated) by 7 °C. To get an insight into the solution conformation of γPNA, circular dichroism (CD) study was carried out. The γPNA strand P1 showed a significant Cotton effect (with a max. at 220 nm and a min. at around 270 nm), suggesting a helical preorganization of the backbone in the single strand (Figure 2b). The CD signal for the duplex P1:2 is similar to that of single strand P1, but showed higher intensity especially at 220 nm. The CD signal enhancement can be attributed to the duplex formation of the γPNAs. Although γPNA is structurally similar to GNA, it is still possible that the structure of γPNA duplex can be different from that of GNA duplex because the amide backbone is conformationally more rigid than the phosphodiestrer backbone.

In summary, inspired by the structure of GNA, we have designed a new artificial nucleic acid composed of neutral amide backbone with structural simplicity and chirality. We were able to gain access to all four types of γPNA monomers in a simple synthetic route. Preliminary studies showed that γPNA seems to form a stable 1:1 duplex with Watson-Crick base pairing. Further systematic studies are in progress on the thermal stability of γPNA in various sequences and length as well as the duplex conformation.
