Security Flaws in Authentication Protocols with Anonymity for Wireless Environments

Jing Xu and Dengguo Feng

ABSTRACT—The emerging wireless networks require the design of new authentication protocols due to their dynamic nature and vulnerable-to-attack structure. Recently, Wu and others proposed a wireless authentication protocol which is claimed to be an improvement of the authentication protocol proposed by Lee and others which provides user anonymity. In this letter, we show that these protocols have a common flaw and that these protocols fail to provide user anonymity. We also propose a modification method to solve this problem.

Keywords—Wireless security, roaming service, anonymity, authentication, key agreement, smart card.

I. Introduction

With the widespread use of mobile devices, wireless roaming is rapidly becoming an important network feature. To provide effective global roaming service for a legitimate mobile user between the home network and a visited foreign network, strong authentication measures are required. When a mobile user (MU) roams to a foreign network, it performs authentication and updates its registration information with its home agent (HA) in the home network, either directly or indirectly. A session key is set up to encrypt further communication in the session between the MU and its foreign agent (FA) in the visited foreign network if the authentication is successful.

Identity anonymity is an important property for roaming services. The disclosure of a user identity may allow unauthorized entities to track his movement history and current location. Any illegal access to information related to users’ location without their permission can be a serious violation of privacy. In 2004, Zhu and others proposed an authentication protocol providing anonymity for wireless environments [1]. In 2006, Lee and others [2] pointed out the weakness of Zhu’s protocol and proposed an improvement. Recently, Wu and others [3] showed that Lee’s protocol does not provide identity anonymity and perfect backward secrecy. They also proposed an improved protocol to repair the security flaws. However, in this letter, we demonstrate that the improved protocol still cannot achieve perfect identity anonymity, contrary to some of the security claims which have been made concerning them. We then present a simple patch which fixes the security problem.

II. Review of Wu’s Protocol

Wu’s wireless authentication protocol [3] is claimed to be an improvement of Lee’s authentication protocol [2] and to provide user anonymity. The protocol includes three phases. In phase I, the HA delivers a password and a smart card for the MU through a secure channel. In phase II, mutual authentication between the MU and an FA is performed through his or her HA. After successful validation, a session key is established, and the MU can obtain service from the FA. In phase III, the MU renews his or her session key with the FA.

1. Phase I: Initiation

When an MU registers with his or her HA, the MU’s identity $ID_{MU}$ is submitted to the HA. Then, the HA delivers the password $PW_{MU}$ and a smart card that contains $ID_{HA}$, $r$, and $h(\cdot)$ to the MU through a secure channel. We calculate $PW_{MU}$ and $r$ as $PW_{MU} = h(N \parallel ID_{MU})$ and $r = h(N \parallel ID_{HA}) \oplus h(N \parallel ID_{MU}) \oplus ID_{HA} \oplus ID_{MU}$, where $N$ is a long random number kept secretly by the HA.

2. Phase II: Mutual Authentication

In this phase, a mutual authentication between an MU and an FA is provided through a secure channel. In phase II, mutual authentication between the MU and an FA is provided through his or her HA. After successful validation, a session key is established, and the MU can obtain service from the FA. In phase III, the MU renews his or her session key with the FA.

i) When an MU enters a new FA, the MU initiates a registration authentication process with the FA in order to identify him or herself to be a legal subscriber of his or her HA. The MU keys his or her password $PW_{MU}$ to the device. Then, the device generates secret random numbers $x_0$ and $x_1$; computes $n = r \oplus PW_{MU}$ and temporary key $L = h(T_{MU} \parallel PW_{MU})$, where $T_{MU}$ is a time stamp; and sends $n$, $(h(ID_{MU})) \parallel x_0 \parallel L$, $ID_{HA}$, and $T_{MU}$ to the FA.

ii) On receiving the message from the MU, the FA checks if the time stamp $T_{MU}$ is valid. If it is valid; the FA generates a secret random number $b$; signs $(b, n, (h(ID_{MU})) \parallel x_0 \parallel x_1, T_{MU}, CERT_{FA})$ using his own private key $PR_{FA}$ to generate $s_i$; and sends $b$, $n$, $(h(ID_{MU})) \parallel x_0 \parallel x_1, T_{MU}, s_i, CERT_{FA}$, and $T_{FA}$ to the HA.

iii) On receiving the messages from the FA, the HA first checks if the signature and time stamp $T_{FA}$ are valid. If they are valid, the HA gets the MU’s real identity by computing $ID_{MU} = h(N \parallel ID_{HA}) \oplus n \oplus ID_{HA}$. Then, the HA computes $h' = h(ID_{MU})$. Next, the HA calculates $L = h(T_{MU} \parallel ID_{HA})$ and uses it to decrypt $(h(ID_{MU})) \parallel x_0 \parallel x_1$. If the decrypted $h(ID_{MU})$ is equal to $h'$, the legal identity of the MU is authenticated. Subsequently, the HA generates a secret random number $c$; encrypts $(h(h(N \parallel ID_{MU})) \parallel x_0 \parallel x)$ with the public key $PU_{HA}$ to generate $e_i$; signs $(b, c, e_i, CERT_{HA})$ using his or her private key $PR_{HA}$ to generate $s_i$; and sends $c$, $e_i$, $s_i$, $CERT_{HA}$, and $T_{HA}$ to the FA.

iv) On receiving the message from the HA, the FA first checks if the signature and time stamp $T_{HA}$ are valid. Next, the FA checks if the received $b$ is the same as its original $b$. If so, the FA issues to the MU the temporary certificate $CERT_{MU}$, which includes lifetime and other information. Next, the FA decrypts $e_i$ with his or her own private key $PR_{FA}$ to obtain $h(h(N \parallel ID_{MU})) \parallel x_0 \parallel x$. Then, the FA computes the session key $k = h(h(h(N \parallel ID_{MU})) \parallel x \parallel x_0)$ and sends $(CERT_{MU}) \parallel h(x_0 \parallel x)$ to the MU.

v) Since $PW_{MU} = h(N \parallel ID_{MU})$, the MU also computes the session key $k = h(h(PW_{MU}) \parallel x \parallel x_0)$. Then, the MU decrypts $(CERT_{MU}) \parallel h(x_0 \parallel x)$ using $k$. If the decrypted $h(x_0 \parallel x)$ is equal to its original value, the legal identity of the FA is authenticated.

3. Phase III: Session Key Renewal

Suppose that the MU needs to renew his or her session key $k_i$ with the FA for the $i$-th time, then the new session key $k_i$ can be obtained as follows.

The MU chooses $x_{i+1}$ randomly and sends $CERT_{MU}$ and $(x_{i-1} \parallel CERT_{MU})_{k_{i-1}}$ to the FA. On receiving the messages from the MU, the FA checks if the certificate $CERT_{MU}$ is valid. If it is valid, the FA decrypts $(x_{i-1} \parallel CERT_{MU})_{k_{i-1}}$. If the decrypted $CERT_{MU}$ is the same as the original $CERT_{MU}$, the integrity of $x_{i+1}$ is verified. Then, the new session key $k_i$ is calculated as $k_i = h(h(h(N \parallel ID_{MU})) \parallel x \parallel x_{i+1})$.

III. Security Weakness in Wu’s Protocol

In mobile networks, to prevent unauthorized entities from tracking a mobile user’s movements and current whereabouts (which may be a serious violation of privacy), it is important to assure user anonymity so that the user’s real identity can only be recognized by the user’s HA, while others can only refer to the user by a pseudonym.

In this section, we demonstrate that Wu’s improved protocol [3] does not provide identity anonymity. Similarly, Lee and Zhu’s original authentication protocols [1], [2] also fall to our attacks.

Assume that MU_A is a malicious mobile user registered with an HA. This MU_A can obtain the identity of any other mobile user MU_i registered with the same HA. The attack proceeds as follows.

i) In the mutual authentication phase, the attacker, MU_A, overhears all the communication flows between MU_i and the FA and obtains n_i.

ii) Since

\[ h(N \parallel ID_i) \oplus h(N \parallel ID_j) \oplus ID_{HA} \oplus ID_i, \]

we have

\[ n_i = h(N \parallel ID_{HA} \parallel ID_i) \oplus ID_i. \]

Similarly,

\[ h(N \parallel ID_{HA} \parallel ID_i) \oplus ID_{HA} \oplus ID_j. \]

Thus, MU_A can obtain the identity of mobile user MU_i from

\[ ID_i = ID_{HA} \oplus \bar{x} \oplus n_i. \]

Furthermore, we show that a malicious outsider \( \bar{x} \), who compromises a mobile user MU_i’s identity, can reveal the identity of any other mobile user MU_j registered with the same HA as MU_i. In particular, \( \bar{x} \) overhears the messages \( n_i \) and \( n_j \) from MU_i and MU_j, respectively. Since

\[ n_i = h(N \parallel ID_{HA} \parallel ID_i) \oplus ID_i \]

and

\[ n_j = h(N \parallel ID_{HA} \parallel ID_j) \oplus ID_j, \]

\( \bar{x} \) can obtain MU_j’s identity by computing

\[ ID_j = ID_{HA} \oplus \bar{y} \oplus n_j. \]

IV. Countermeasure

Our attack exploits the fact that the same random number \( N \) is chosen by the HA for different mobile users registered with the HA. Thus, the patch is fortunately simple.

In the initiation phase, the HA generates a different random number \( N_{MU} \) for each mobile user and computes \( PW_{MU}, r_{MU}, \) and \( n_{MU} \) as

\[ PW_{MU} = h(N_{MU} \parallel ID_{MU}). \]

\[ r_{MU} = h(N_{MU} \parallel ID_{HA}) \oplus h(N_{MU} \parallel ID_{MU}) \oplus ID_{HA} \oplus ID_{MU}. \]

\[ n_{MU} = PW_{MU} \oplus r_{MU}. \]

Then, the HA delivers the password \( PW_{MU} \) and a smart card, which contains \( ID_{HA}, r_{MU}, \) and \( h() \), to the MU through a secure channel. The HA also records the mapping relation of the MU’s \( n_{MU} \) and \( N_{MU} \) (\( n_{MU} \leftrightarrow N_{MU} \)). In the mutual authentication phase, the HA gets the MU’s real identity by computing

\[ ID_{MU} = h(N_{MU} \parallel ID_{HA}) \oplus n_{MU} \oplus ID_{HA}. \]

With this modification, the message \( n_{MU} \) sent by the MU in each run of the protocol becomes bounded to the identity \( ID_{MU} \) and \( N_{MU} \) of the MU; therefore, such an attack as that previously presented would be impossible.

V. Conclusion

In this letter, we demonstrated that Wu’s wireless authentication protocol [3] fails to provide perfect identity anonymity, and it is easy to extend the result to the original versions [1], [2]. We have also demonstrated how to fix the protocol to ensure that it is robust against attacks.
