Received for publication July 25, 2008; accepted March 20, 2009

SUMMARY

An attempt has been made to assess whether the dose dependent effect of benzene extract of *Ocimum sanctum* leaves on the morphological changes in the cauda epididymal spermatozoa and sperm parameters in male albino rats. Scanning Electron Microscope observations illustrate the disturbance in plasma membrane as well as acrosomal membrane. Most of the sperms appear morphologically abnormal in the mid region of the tail; there is formation of balloon like cytoplasmic droplet. Sperm parametric study exhibits decrease in the total sperm count, sperm motility, forward velocity and increase in the percentage of abnormal sperms in dose dependent manner on treatment benzene extract of *Ocimum sanctum* leaves. The results suggest that the effects may have resulted from a general disturbance in the proteins and alteration in cauda epididymal milieu probably due to androgen deficiency consequent upon antiandrogenic property of *Ocimum sanctum* leaves.

Key words: *Ocimum sanctum*; Cauda epididymis; Spermatozoa; Scanning Electron Microscope; Albino rats

INTRODUCTION

The plant products affecting aspects of male reproduction, brings about the effect through either of two mechanisms namely, estrogenic or antiandrogenic effect (Kasinathan et al., 1972). The leaves, flowers, fruits and seeds of several plants are known to possess estrogen and antiandrogen like substances, which act on the reproductive system of male and female rats and thus inhibiting fertility (Chinoy and Geetha Ranga, 1983; Malini et al., 1985; Akbarsha et al., 1990; Aladakatti and Nazeer Ahamed, 1999). From the literature of medicinal plants, it has been established that different parts of the plant source causes reduction in sperm count, sperm motility and increase in relative percentage of the abnormal sperm in mouse and rats (Chinoy et al., 1995; Akbarsha and Averal, 1996; Aladakatti et al., 2001; Girini et al., 2005) and results shown that androgen is essential for the maturation, motility and survival of sperms in the epididymis. *Ocimum (O.) sanctum* Linn. (Laiatae family) is an important medicinal plant, commonly called tulsi, has been recognized for its unique properties. It is used as antibacterial,
insecticidal, diaphoretic in malarial fever, antiperiodic in gastric and genitourinary systems (Nadkarni, 1954; Kirtikar and Basu, 1975). Additionally, the leaves of *O. sanctum*; a) significantly altered the weight of testis, reducing the sperm count and motility (Seth et al., 1981); b) cause a decrease in pH, hypertonic environment and differences in concentration of chemical substances of biological importance i.e., mucoprotein, alkaline phosphatase and acid phosphates (Kashinathan et al., 1972); c) reduce the mating behaviour of both male and female albino rats (Khanna et al., 1986; Kantak and Gogate, 1992; Sardessai et al., 1999); and d) significantly altered the sperm count, motility, velocity and fructose contained in the cauda epididymis of male albino rats (Mukhtar Ahmed et al., 2002). The review of literature indicates that the ultra structural studies on the effect of dose dependent of benzene extract of *O. sanctum* leaves on the morphological changes in the sperms of albino rats is lack. Hence, the present study was aimed to elucidate the effect of different concentrations of benzene extract of *O. sanctum* leaves on sperm parameters and morphological changes in the rat cauda epididymal sperms by scanning electron microscope.

**MATERIALS AND METHODS**

**Preparation of test material**
Fresh *O. sanctum* leaves were collected and dried in shade. A voucher specimen (Zoo/herb/File No.47-Acc.No.22) was deposited at Zoology Department, Karnatak University, Dharwad, India. The dried leaves were coarsely powdered and subjected to soxheltation process to get the benzene extract. Extract thus obtained was allowed to dry and stored in a dessicator at 4°C.

**Animals and treatment**
Colony bred healthy adult male albino rats (Wistar strain) weighing 180 - 200 g were utilized for experiments. All animals were proven fertility and obtained from the rat colony maintained in the department. They were housed at a temperature of 26 ± 2°C and exposed to 13 - 14 h of daylight and maintained on a standard diet and water was given ad libitum. The benzene extract is then mixed with propylene glycol as required and administered orally (gavage) to the experimental animals (WHO, 1983).

**Study protocol**
The rats were divided into 4 groups; each consisting of 5 animals is as Group I: Control animals received equal volume of equivalent concentration of propylene Glycol orally for 15 days. Group II: The animals were given a daily dose of 150 mg/kg body weight of benzene extract in 1.5 ml of propylene Glycol for a period of 15 days. Group III: The animals were given a daily dose of 200 mg/kg body weight of benzene extract in 2 ml of propylene Glycol for a period of 15 days. Group IV: The animals were given a daily dose of 250 mg/kg body weight of benzene extract in 2.5 ml of propylene Glycol for a period of 15 days. The animals were sacrificed by cervical dislocation 24 h after the last dose.

**Sperm analysis**
The cauda epididymis was chopped into phosphate buffered glucose saline (PBGS) [composition: NaCl 50 mM; Na₂HPO₄ 200 mM; glucose 200 mM and KH₂PO₄ 26 mM]. The debris was removed and a clear suspension, viz; the epididymal plasma was used for the analysis of total sperm count, sperm motility, forward velocity and relative percentage of abnormal sperms in male albino rats.

The total sperm count and motility were calculated according to the method of Besley et al. (1980) using Neubauer’s haemocytometer. Briefly, to increase the accuracy of sperm count, the epididymal plasma was diluted with a spermicidal solution, prepared by dissolving 5 g of sodium bicarbonate (NaHCO₃) and 1 ml of 40% formaldehyde in 100 ml of normal saline. A twenty times dilution
was made using W.B.C pipette, which was thoroughly mixed and one drop was added to both sides of Neubauer haemocytometer. The spermatozoa were allowed to settle down in the haemocytometer by keeping them in a humid chamber for one hour. The sperm count was done in R.B.C counting 5 major squares. The total number of sperms were counted in all the major squares and calculated as follows:

\[
\text{Total number of sperms/ml plasma} = \frac{\text{Total number of sperms per square}}{\text{Total volume per square}} \times 10^4 \times \text{dilution factor}\ (20)
\]

Similarly the total number of motile sperms was calculated, using phosphate buffer saline instead of spermicidal solution. The forward velocity of the sperm was calculated according to the method of Ratnasooriya (1984). Briefly, the epididymal plasma was suspended in phosphate buffer saline, cleared the tissue debris and a clear solution was used for the assessment of average forward velocity of sperms. The assessment was made under light microscope, fitted with a movable mechanical stage and a calibrated ocular micrometer, at 400 × magnification. A drop of sperm suspension was transferred to a clean glass slide and the initial place and time of each sperm was recorded. The time taken for forward movement of sperm from the initial place within microscopic field was recorded using a stop watch. The procedure was repeated for 10 spermatozoa in each sample and the average forward velocity of sperm was calculated and expressed as mm/s. The relative proportion of abnormal sperms was analyzed according to the method of Bauer et al. (1974). Briefly, equal volume of cauda epididymal plasma and 5% NaHCO₃ were taken in a centrifuge tube, mixed well and centrifuged for 5 min at 4,000 × g. The supernatant was discarded and to the precipitate 5 ml of normal saline was added, mixed well and centrifuged again. The procedure was repeated 2 to 3 times and a clear precipitate was obtained. To the final precipitate few drops of normal saline were added, mixed thoroughly and a smear was prepared on a clean slide. The smear was dried at room temperature, fixed by heating it over the flame for two to three seconds. Then the smear was flushed with 95% alcohol, drained and dried. It was stained in Ziehl Neelson’s Carbol Fuchs in diluted with equal volume of 95% alcohol for 3 min and counter stained with 1:3 (v/v) aqueous solution of Loeff er’s methylene blue for 2 min. After staining, the smear was rinsed in water and dried in air. The abnormal sperms included categories like double tailed, detached head, detached tail, mid piece bending and irregular head. The relative proportion of the normal and abnormal sperms was from the smear and expressed in terms of percentage.

**Scanning electron microscopic (SEM) study**

Twenty-four hours after the last dose, the control and treated animals were sacrificed by cervical dislocation. Preparation of rat spermatozoa for SEM studies was per formed as described elsewhere (Aladakatti and Nazeer Ahamed 1999). Briefly, a drop of cauda epididymal plasma was fixed in 2% glutaraldehyde, centrifuged and washed with 0.1 M Sodium cacodylate buffer (pH7.2), centrifuged again in distilled water till the buffer solution was washed out and a thin film was applied on a cover slip, dried, sputter coated with gold and finally observed under scanning electron microscope (Model. LEO 435 VP Detector SL.1. LEO Electron Microscopy ltd Cambridge, England) at Central Food and Technological Research Institute, Mysore (India).

**Statistical analysis**

The data were presented as mean ± S.E.M. The comparison of data for statistically significant differences was done using students ‘t’ test and a probability level of \( P \leq 0.01 \) and \( P \leq 0.001 \) were considered as significant and highly significant, respectively.
RESULTS

Sperm analysis
Analysis of sperm parameters, such as total sperm count, total number of motile sperm, forward velocity of the sperm and percentage of abnormal sperm of the cauda of epididymal plasma were carried out in the control and all the treated animals. The control rats showed $56.40 \times 10^4$ total numbers of sperm/ml epididymal fluid, $52.40 \times 10^4$ numbers of motile sperm/ml epididymal fluid with a speed of 127.63 mm/s and 11.40% of abnormal sperm were recorded (Table 1).

Where as in the benzene extract of *O.sanctum* leaves treated animals (Group II, III and IV), the abnormal sperm in cauda epididymal plasma of albino rats are doses dependent. With a dose of 150 mg/kg body weight of benzene extract treated animals (Group II), showed a significant ($P \leq 0.01$) decrease in total sperm count (75%), total number of motile sperm (75%) and forward velocity of the sperm (86%). There was a highly significant ($P \leq 0.001$) increase in the percentage of abnormal sperm (37.3%).

While, in dose of 200 and 250 mg/kg body weight of benzene extract treated animals (Group III and Group IV, respectively), showed a highly significant decrease ($P \leq 0.001$) in total sperm count (65% and 56%, respectively), total number of motile sperm (58% and 45%, respectively), forward velocity of sperm (62% and 49%, respectively) and a highly significant increase ($P \leq 0.001$) in the percentage of abnormal sperm (47.0% and 54.4%, respectively) when compared to control animals.

SEM observations of rat sperms from cauda epididymal plasma
Electron Microscopic observations of the cauda epididymal sperm of control rats (Group I) showed normal parts (Fig. 1). Perforatorium and acrosome are covered with the plasma membrane. A distinguish acrosome is covered with acrosomal membrane. The whole spermatozoon is intact with all the membranes and organelles.

*$P \leq 0.01$, **$P \leq 0.001$. 
Whereas in the benzene extract of *Ocimum sanctum* leaves treated animals (Group II, III and IV), the severity of morphological changes are dose dependent. With a dose of 150 mg/kg body weight of benzene extract treated animals (Group II), there is slight disturbance in the plasma membrane as well as in the acrosomal membrane and there is slight dorsoventral constriction (arrows) in the head region of spermatozoon. 4.39kx.

![Image of spermatozoon](image1)

**Fig. 2.** EM of spermatozoon of rats treated with 150 mg/kg body weight of benzene extract. There is slight disturbance in the plasma membrane as well as in the acrosomal membrane and there is slight dorsoventral constriction (arrows) in the head region of spermatozoon. 4.39kx.

With a dose of 200 mg/kg body weight of benzene extract treated animals (Group III), most of the sperms exhibit abnormal features morphologically such as head with membrane disruption (Fig. 3) and agglutination and cytoplasmic bulging/droplet are seen distinctly in the mid portion of sperms tail (Fig. 4). Further, the maximum dose of 250 mg/kg body weight of benzene extract treated animals (Group IV), results in head of spermatozoa with distinct indication of severe effect at the anterior region. The plasma membrane along the entire length of sperm head is disrupted, the middle region of the sperm head is constricted dorsoventrally and there is serration at the connective piece of the spermatozoa (Fig. 5). Increase in the agglutination of sperm with cytoplasmic bulging/droplet are seen distinct visibility of balloon like in the mid portion of the most spermatozoa (Fig. 6).

**DISCUSSION**

Various plants like chloroform extracts of the bark of *Quassia amara* (Parveen et al., 2003); hydroalcoholic extract from *Lantana camara* leaves (de Mello et al., 2003); aqueous crude extract of the bark of *Carica papaya* (Kusemiju et al., 2002); aqueous extracts of *Ruta graveolens* (Khoury and El-Akawi, 2005);
methanol sub-fraction of the seeds of *Carica papaya* (Lohiya *et al.*, 2006); methanol extract of *Dendrophthoe falcate* (Gupta and Kachhawa, 2007); aqueous extract of *Peganum harmala* (El-Dwairi and Banihani, 2007); marjoram volatile oil and grape seed extract on ethanol administration (El-Ashmawy *et al.*, 2007) have been reported to possess antifertility activity by exhibiting reduced the sperm count, motility, fertility, viability and increased abnormal sperms in mice and rats. It was suggested that the extract causes androgen depletion at the target level, particularly in the cauda epididymis thereby affecting physiological maturation of the sperm (Chinoy *et al.*, 1995).

Studies involving hypophysectomy, castration and androgen replacement therapy reveal that androgen is essential for physiological maturation and survival of the spermatozoa in the epididymis (Dyson and Orgebein-Crist, 1973; Setty *et al.*, 1977). It is known that sperm reproduction doesn’t proceed optimally to completion without a continuous androgen supply (Brooks, 1981). Androgen may affect the sperm directly or through modification of epididymal milieu. Several facts suggest a direct effect on the organ (Blaquier, 1971). It has been shown that androgens are essential for survival and motility of spermatozoa in the rat epididymis, cauda region appears to be the most favourable site. Sperm possess two principal attributes, viz, motility and the fertilizing ability, which are prerequisites for fertilization. Any negative impact on motility would seriously affect the fertilizing ability (Murugavel *et al.*, 1989).

In the present study, on treatment with benzene extract of *O. sanctum* leaves exhibits reducing sperm count, motility and sperm speed in dose dependent manner. It was suggested that the extract causes androgen depletion at the target level, particularly in the cauda epididymis thereby affecting physiological maturation of the sperm (Chinoy *et al.*, 1995). In this study, the observations made and are supported from studies of Chloroform extract of the bark of *Quassia amara* (Parveen *et al.*, 2003); aqueous crude extract of the bark of *Carica papaya* (Kusemiju *et al.*, 2002); purified compounds and methanol sub-fraction of the seeds of *Carica papaya* (Lohiya *et al.*, 2005, 2006); methanol extract of *Dendrophthoe falcate* (Gupta and Kachhawa, 2007); aqueous extract of *Peganum harmala* (El-Dwairi and Banihani, 2007) and marjoram volatile oil and grape seed extract on ethanol administration (El-Ashmawy *et al.*, 2007).
The occurrence of morphologically abnormal spermatozoa is a diagnostic aid for infertility besides using other characteristics such as motility, density and viability. Semen sample per ejaculate containing more than 20% of abnormal sperm is considered poorly fertile (Bauer et al., 1974). A high incidence of abnormality is associated with infertility (Macleod, 1970). The relative distribution of the different morphological types of spermatozoa present in a sample provides the most significant clue to discriminate between fertile and infertile samples (Gopalkrishnan et al., 1992). Sperm movement is reportedly different between morphologically normal and abnormal spermatozoa (Katz et al., 1982). The assessment of morphology is good indicator of fertilizing ability of spermatozoa and the increased incidence of headless spermatozoa in the infertile group confirms that this is associated with infertility (Rogers et al., 1983; Gopalkrishnan et al., 1989).

In the present study, on treatment with benzene extract of *O. sanctum* leaves exhibits significant increase in sperm anomalies viz., Head abnormalities were amorphous, hookless, banana-shaped, formation of folded, coiled and bent. Incidences of abnormal sperms were found elevated by dose dependent. Besides these morphological alterations, many sperm tails appeared in the smears of treated rats with detached heads. The present study is supported from studies of treated with chloroform extracts of the bark of *Quassia amara* (Parveen et al., 2003); hydroalcoholic extract from *Lantana camara* leaves (de Mello et al., 2003); aqueous crude extract of the bark of *Carica papaya* (Kusemiju et al., 2002); aqueous extract from leaves of *Achillea millefolium* (Dalsenter et al., 2004); purified compounds of the seeds of *Carica papaya* (Lohiya et al., 2005).

Androgens are essential for survival and motility of spermatozoa in the rat epididymis. Sperm motility is an important attribute of sperm quality as there is a good correlation between sperm motility on one hand and plasma membrane integrity and conception rates on the other. The combination of medroxy progesterone acetate and testosterone enanthate is a contraceptive, which causes loss of sperm motility and structural defects exerted by changing the membrane permeability in monkey epididymis (Rajalakshmi et al., 1990). There is an evidence of acrosomal loss or damage as well as other abnormalities observed in caudal region of rat sperm due to this treatment suggesting that these sperms were probably unable to fertilize the ovum (Rao and Roy, 1993).

The acrosome contains several enzymes which are secreted by the Golgi apparatus and endoplasmic reticulum. The production of enzymes destined for the acrosome is regulated to some degree by testosterone (Morton, 1975). From histochemical evidence the presence of carbohydrates or polysaccharides in the head of the spermatozoa, which are associated with various enzymatic activities is indicated. Earlier studies have been reported that morphological changes in the head of spermatozoa in general and the acrosome in particular may have resulted from an alteration in the epididymal milieu of rats treated with crude leaf extract of *A.indica* (Aladakatti and Nazeer Ahamed, 1999) and alcohol seed extract of *Momordica charantia* (Girini et al., 2005) suggested that these changes are due to a general disturbance of carbohydrates or polysaccharides present in the acrosome of the sperm head (Aladakatti and Nazeer Ahamed, 1999). In this study, most of the sperm abnormalities are dose dependent. The mid region of sperm heads show dorsoventrally constricted with the bulged sub acrosomal material. The disrupted plasma membrane and acrosomal membrane particularly at the anterior region, on treatment with benzene extract of *O. sanctum* leaves, are probably due to the general disturbance in the proteins.

Studies have been reported that extracts from different plants namely gossypol, *Solanum xanthocarpum*, *Carica papaya* causes the sperm abnormalities by exhibiting acrosomal damage and mid-piece anomalies which results in complete inhibition of
fertility in rats and mice (Rao, 1988; Chinoy et al., 1995). Aqueous crude extract of *Echeveria gibbiflora* on guinea pig sperm results the formation of a huge bubble by distension of the plasma membrane and dispersion of the acrosome content with disappearance of the external acrosomal membrane at the sperm head level (Delgado et al., 1999). Triptolid isolated from *Tripterygium wilfordii* has been reported to cause all cauda epididymal sperm to exhibit a complete absence of the plasma membrane over the entire middle and principal piece and premature decondensation of the nuclei in rats (Hikim et al., 2000). Recent studies of a chloroform extract of *Carica papaya* seeds (Lohiya et al., 2002); a hydroalcoholic extract of *Lantana camara* leaves (de Mello et al., 2003); crude extract of *A.indica* leaves (Aladakatti and Nazeer Ahamed, 2005) and aqueous decoction of *Chenopodium album* seeds (Kumar et al., 2007) in rats and rabbits shown morphological abnormalities in the head of spermatozoa along with mid-piece anomalies. It has been suggested that the extract might cause an androgen deprived effect to target organs resulting in alterations in the internal milieu, especially of cauda epididymis (Chinoy et al., 1995).

In the present study of treated animals showed that the tail portion has balloon like cytoplasmic droplet. Ejaculates containing a high proportion of spermatozoa with attached cytoplasmic droplet can be correlated with altered epididymal function and reduced fertility (Cummins, 1973; Bedford, 1976). In the present study, high proportion of spermatozoa with attached cytoplasmic droplets in treated animals may be due to altered epididymal function. Similar observations were made in studies of combination of progesterone and androgen, *Carica papaya*, vincristine and cytotoxic and xenobiotic agents treated rats (Rao and Roy, 1993; Chinoy et al., 1995; Akbarsha and Averal, 1996; Akbarsha et al., 2000). A recent studies of aflatoxin B (1), a food borne mycotoxin and alcohol seed extract of *Momordica charantia* revealed that a higher percentage of cauda epididymal spermatozoa retained the cytoplasmic droplets in the albino mouse and rats respectively (Agnes and Akbarsha, 2003; Girini et al., 2005). The sperm cytoplasmic droplets contained electron-dense spherical inclusions, which were hypothesized as lipid inclusions produced from the lamellae through the spherical vesicles of the cytoplasmic droplets (Agnes and Akbarsha, 2003). It is known that spermatozoa carrying cytoplasmic droplets would be inhibited in motility and may not fertilize the ova (Hermo et al., 1988).

Thus, in present study, based on SEM and sperm parameter observations, it can be suggested that morphological changes in the head and tail region of cauda epididymal spermatozoa and changes in sperm parameters in male albino rats on different concentration treatment with benzene extract of *O. sanctum* leaves may be due to general disturbance of proteins and alteration in the epididymal milieu probably due to androgen deficiency consequent upon the antiandrogenic property of benzene extract of *O. sanctum* leaves. However, these conclusions are based on the preliminary study, where the rats are force fed with the benzene extract of *O. sanctum* leaves. More refined and sophisticated study is needed for identification of active constituents present in the benzene leaf extract and their effects on androgen dependent parts of the spermatozoa in albino rats which are under progress.
