Abstract

Epithelial cysts are benign epithelium-lined lesions that contain fluid or semisolid material. Most epithelial cysts in the oral cavity occur in the anterior part of the mouth floor. Cysts arising on the uvula in a cleft palate patient are rare. Intraoral examination in a 14-month-old boy with a complete cleft lip and palate revealed a cystic lesion on the right uvula. The lesion was excised and push-back palatoplasty with Z-plasty on the uvula was performed. Histopathological examination diagnosed an epithelial cyst. We report a case of an epithelial cyst of uvula in a patient with a unilateral complete cleft lip and palate.

Key words: Epithelial cyst, Cleft palate, Uvula, Soft palate

Introduction

Epithelial cysts are benign lesions with epithelial lining containing fluid or semisolid material. These lesions can be found on any part of the body, although 6.9% of them appear at head and neck area and only 1.6% are seen in the oral cavity[1,2]. Most cysts occurring in the oral cavity are located at the anterior part of the mouth floor, and the soft palate or uvula is an unusual site[3-6]. There is no report of an epithelial cyst of the uvula in a cleft palate patient. We present a rare case of an epithelial cyst on the uvula with a cleft lip and palate, with a literature review.

Case Report

The patient was a 14-month-old male infant with unilateral complete cleft lip and palate on the left side, with no other remarkable medical history. He underwent primary cheiloplasty using the triangular flap procedure at the age of 4 months and revisited our clinic for palatoplasty. Clinical examination revealed a mucosal bulging on the right uvula with a smooth, yellow-whitish surface (Fig. 1). There were no other pathological findings in the oral cavity.

Under general anesthesia, the cystic lesion on the right uvula was surgically excised for histopathological examination. The Z-plasty was performed to correct the size differences of each uvula. Push-back palatoplasty was then performed. The excised cystic lesion was separated easily with oval shape measured 4×4 mm size (Fig. 2).

Microscopic examination of the specimen sections at high magnification revealed small cystic lesions within the
surrounding mucosal surface consisted of stratified squamous epithelium and ciliated cuboidal-to-columnar epithelium (Fig. 3). There was no evidence of skin appendages or sweat or sebaceous glands in the cyst.

Discussion

Epithelial cysts are slowly enlarging painless lesions, either congenital or acquired. The congenital cysts are called epithelial cysts, and the acquired cysts are known as implantation or post traumatic cysts[3]. For differential diagnosis of this type of cystic lesion, epidermal cyst, dermoid cyst, inclusion cyst, branchial cleft cyst, and mucous cyst should be considered, but these lesions can be diagnosed with certainty only by histological examination[5,7-9]. An epithelial cyst in the oral cavity was first reported in 1970[3], and a few epithelial cysts on the soft palate or uvula were reported[4,6,9].

The origin of epithelial cysts is uncertain. However, the most convincing hypothesis is that the cyst originates from ectodermal debris, separated during the midline closure of embryonic fissures[7]. This hypothesis was supported by an experiment that successfully produced a dermoid cyst in the laboratory[10]. Most epithelial cysts seen in the oral cavity, pharynx, and cervical area are presumed to develop from separated ectoderm during the fusion process between the first and second branchial arches. Some of the epidermoid cysts arising in oral cavity can result from the fusion of the lateral processes on either side of the first branchial arch[1,6,7]. Epithelial cysts occurring in the soft palate and uvula probably originate from the fusion of the palatine plates.

Most of the lesions are asymptomatic, but in some cases, enlarged cystic lesions can cause air way obstruction, sonorous respiration, gagging or dysphagia[5,9]. The surgical excision of the epithelial cyst is diagnostic and treatment method at the same time, and no obvious complications have been reported[6,7].

This is an interesting case in which the epithelial cyst was on the uvula, a rare location, with a cleft palate patient. We recommend a careful clinical examination of the soft palate or uvula for patients with cleft palate to detect a cystic lesion at a rare location.
