ABSTRACT

We present $^{12}$CO J = 2–1 line observations of G54.1+0.3, a composite supernova remnant with a mid-infrared (MIR) loop surrounding the central pulsar wind nebula (PWN). We map an area of 12$''$×9$''$ around the PWN and its associated MIR loop. We confirm two velocity components that have been proposed to be possibly interacting with the PWN/MIR-loop; the +53 km s$^{-1}$ cloud, which appears in contact with the eastern boundary of the PWN and the +23 km s$^{-1}$ cloud, which has CO emission coincident with the MIR loop. However, we have not found a direct evidence for the interaction in either of these clouds. Instead, we detected an 5$''$-long arc-like cloud at +15+$^\pm$23 km s$^{-1}$ with a systematic velocity gradient of ~3 km s$^{-1}$ arcmin$^{-1}$ and broad-line emitting CO gas with widths (FWHM) of ~7 km s$^{-1}$ in the western interior of the supernova remnant. We discuss their association with the supernova remnant.

Key words: ISM; individual(G54.1+0.3) — ISM: molecules — radio lines: ISM — supernova remnants

1. INTRODUCTION

G54.1+0.3 is a young, core-collapse supernova remnant (SNR). The remnant has a central PWN with a 136 ms radio/X-ray pulsar (PSR J1930+1852) at the center of the nebula (Lu et al. 2002). The characteristic age of the pulsar is 2,900 yr. The remnant has been known as a Plerion or Crab-like SNR of 120$''$×80$''$ in size because of the central PWN. Recently, Lang et al. (2010) detected a faint radio emission with a diameter of ~10$''$ surrounding the PWN, and proposed that the emission was from the SNR shell driven by the supernova (SN) ejecta of G54.1+0.3. Another evidence supporting the SNR shell scenario was provided by Bocchino et al. (2010), who detected diffuse, thermal X-ray emission filling the radio shell. The observational evidence suggests that G54.1+0.3 is a composite SNR, which has a central PWN and a surrounding extended SNR shell. The estimated distance to the SNR ranges from 6 to 9 kpc (see Section 4).

A MIR loop surrounding the central PWN detected in G54.1+0.3 has been detected by Koo et al. (2008). The loop is partially complete, and is elongated along the northwest-southeast direction. It has an extent of ~105$''$×54$''$ and surrounds the southern part of the PWN. There are eleven stellar sources with strong MIR excesses embedded in the loop. Koo et al. (2008) showed that they are OB-type stars and, based on their mid/far-infrared excesses and spatial confinement in a loop-like structure surrounding the PWN, proposed that they are young stellar objects whose formation was triggered by the progenitor of the SNR. Later, Temim et al. (2010) carried out Spitzer spectroscopic observation of the MIR shell, and detected dust emission with a bump at 21 μm. This feature is similar to the emission of freshly-formed SN dusts detected in the young SNR Cassiopeia A. Motivated by the pronounced feature and the detected broad emission lines, Temim et al. (2010) proposed that the stellar objects are the members of a star cluster, to which the SNR progenitor belongs, and IR emission comes from the SN dust. So there are two scenarios for the nature of the MIR loop and the stellar objects.

In this paper, we present $^{12}$CO J=2–1 emission line observations of the IR loop and the surrounding area. The molecular environment is expected to be quite different for the two scenarios, so that the observation will be useful in understanding the nature of the IR loop and the stellar sources. Koo et al. (2008) has found that there is a faint $^{13}$CO J = 1–0 emission coincident with the IR loop in the Boston-University-Five College Radio Astronomy Observatory Galactic Ring Survey (Jackson et al. 2006). They proposed that this molecular cloud could be associated with the SNR. On the other hand, Leahy et al. (2008), using the same survey
data, found that there was a CO cloud that appears to be blocking the eastern boundary of the PWN and proposed that this cloud is interacting with the SNR. Both prepositions are based on circumstantial evidence and the association needs further investigation. Recently γ-ray emission has been detected toward the PWN, which could be partly due to the decay of neutral pions produced in the interactions of pulsar-accelerated nuclei with one of these molecular clouds (Li et al. 2010; Acclarci et al. 2010). Our observation, however, has not detected a direct evidence for the interaction between the PWN and both clouds. We present our observation in next sections.

2. OBSERVATIONS

$^{12}$CO $J=2-1$ mapping observations of G54.1+0.3 were done in February and March, 2008 using a 230 GHz SIS mixer receiver (Lee 2008) newly installed on the 6-m telescope at Seoul Radio Astronomy Observatory (SRAO). The new 210–265 GHz band receiver shows quantum-limited noise performance. It employs a RF and an IF quadrature hybrid for sideband rejection and supports dual-polarization observation. At the time of initial operation, only single polarization mode was supported. The observation of G54.1+0.3 was the first science observation after commissioning runs of the new receiver system. An autocorrelation spectrometer was configured to cover 100 MHz with 2048 channels, which corresponds to 130 km s$^{-1}$ velocity coverage. The system temperature was 200–400 K and the typical rms noise level of the spectra is $\sim 0.13$ K at 0.21 km s$^{-1}$ velocity resolution. All the spectra presented in this paper have been re-gridded to 0.21 km s$^{-1}$ velocity resolution to match the $^{13}$CO $J=1-0$ data from the Galactic Ring Survey (Jackson et al. 2006). The main beam efficiency of the telescope $\eta_{mb}$, measured using Mars, is about 0.51 at 230 GHz. We use $T_{mb} = T_A / \eta_{mb}$ for temperature scale throughout this paper, if not otherwise stated. The mapped area is $12' \times 9'$ around the remnant G54.1+0.3, centered at $(\alpha, \delta)_{2000} = (19^{h}30^{m}30^{s}.13, +18^\circ52'44'')$. The spectra were obtained at a grid spacing of 30". The beam size of the SRAO telescope at 230 GHz is 48". In the Galactic Ring Survey, $^{13}$CO data were obtained at 22" grid spacing and beam width of 46". We have re-sampled the $^{13}$CO data cube with 30" grid spacing using the Miriad data analysis package.

3. RESULTS

3.1 Overall Distribution of CO Gas

Fig. 1 shows the average spectrum of $^{12}$CO $J = 2-1$ over the observed region with the corresponding $^{13}$CO $J = 1-0$ spectrum obtained from the Galactic Ring Survey overlaid. Between $v_{LSR} = 0$ and 60 km s$^{-1}$, distinct spectral components appear at 2, 8, 23, 32, 40 and 53 km s$^{-1}$ in the $^{12}$CO spectrum. In the bottom panel of the figure, we show the relation between the distance and LSR velocity according to the
rotation curve of (Brand & Blitz 1993), which is close to the flat rotation curve with $R_\odot = 8.5$ kpc and $\Theta_\odot = 220$ km s$^{-1}$. Note that there are two corresponding distances for a given positive LSR velocity, i.e., +23 km s$^{-1}$ component could be either at 1.8 kpc or at 8.2 kpc. The maximum LSR velocity at this Galactic longitude ($54.5^\circ$) is about 43 km s$^{-1}$ according to this model. Some observations, however, suggest that the maximum rotation velocity toward this Galactic longitude is somewhat higher than 220 km s$^{-1}$ (see Leahy et al. 2008, and references therein), so the +53 km s$^{-1}$ component may be near the tangential point which is 6.9 kpc assuming the above Galactocentric distance and Galactic rotational velocity at the Sun.

The integrated intensity maps for the velocity intervals of every $5-9$ km s$^{-1}$ in the range between 15 and 55 km s$^{-1}$ are presented in Fig. 2. At $v_{\text{LSR}} = 15-21$ km s$^{-1}$, there is a faint arc-like cloud elongated along the north-south direction in the western side of the PWN. As will be shown below, this arc-like cloud (hereafter ‘Arc Cloud’) has a large line width and a systematic velocity gradient along the cloud. At $v_{\text{LSR}} = 21-24$ km s$^{-1}$, there is strong, extended emission superposed on the PWN. It has a rather complex morphology with several peaks. Between $v_{\text{LSR}} = 24$ and 43 km s$^{-1}$, CO clouds appear in the surrounding area, i.e., in the western and southeastern areas at 24–29 km s$^{-1}$ and 30–43 km s$^{-1}$, respectively. Because they are well separated from the PWN/IR-loop and extend beyond the SNR boundary, they are not considered to be possibly associated with the PWN (see Section 3.2). At 45–60 km s$^{-1}$, there is another thick, arc-like cloud that appears in contact with the eastern boundary of the PWN. This is the cloud that was proposed to be interacting with the PWN by Leahy et al. (2008). In the following, we first investigate the properties of the +53 km s$^{-1}$ component and then the +23 km s$^{-1}$ component.

### 3.2 +53 km s$^{-1}$ Cloud

Fig. 3 shows the channel maps of the +53 km s$^{-1}$ cloud. In the figure, we overplot the contours of the $^{13}$CO 1–0 emission at the corresponding velocities, which are noted in each panel. The cloud is composed of three clumps of a few arc-minute extent - a southern brightest one centered at 53.9 km s$^{-1}$, a faint middle one at 53.5 km s$^{-1}$, and a northern clump with moderate brightness at 54.3 km s$^{-1}$. The northern one is superposed with another filamentary cloud in the northern area at a slightly lower velocity (52.6 km s$^{-1}$). As pointed out by Leahy et al. (2008), the PWN nebula is located in the middle where the cloud appears to kink. However, we do not see any indication of the interaction in the line profiles of this cloud (Figure 4). The ratio $^{12}$CO(2–1)/$^{13}$CO(1–0) ($R_{2/1,10}$) $\approx$ 5 which is a typical value for a calm molecular cloud (e.g., see Sakamoto et al. 1994).

An interesting feature is the weak ($\sim$ 1 K) emission
between 45 and 55 km s^{-1} in the eastern area of the +53 km s^{-1} cloud. As shown in Fig. 4, the CO line profiles are broad (∼ 10 km s^{-1}) although there seems to be more than one component. Because the emission region extends beyond the eastern boundary of the outer mapping area, we could not determine the full extent. The association of the broad emission with the +53 km s^{-1} cloud is not clear because the two clouds are connected by the faint emission in the middle. Since the radio boundary of the G54.1+0.3 SNR appears quite circular and the broad emission extends beyond the boundary, we consider that this component is not related to the SNR. (The radio filaments outside the SNR shell shown in Fig. 4 of Lang et al. (2010) are believed to belong to a much larger-scale structure. See Figs. 1–2 of Leahy et al. (2008).) Instead, there is a star-forming infrared filament in the Spitzer MIPS 24 μm image that is spatially coincident with the broad CO emission as well as the 30–38 km s^{-1} CO emission in Fig. 2, and we suspect that the broad CO emission is associated with this filament.

3.3 +23 km s^{-1} Clouds

The 12CO emission structure of the 23 km s^{-1} cloud shown in Fig. 5 is rather complicated. It is helpful to look at the 13CO map first. In Fig. 6, we show R_{21}/R_{10} ratio map with the 13CO intensity contours overlaid. The ratios are derived in each channel for the pixels with T_{mb,13} ≥ 0.35 K, which corresponds to 5σ level.

Note that the ratios are small where 13CO emission is strong. It becomes less than 1 at 13CO peaks. This is an indication of self-absorption by relatively cold CO gas in front of warmer CO gas. The self-absorption is also apparent in the line profiles where we see a dip or a plateau in the 12CO profiles at which the 13CO intensity has maximum (Fig. 7). The 13CO intensity contour maps suggest that the 13CO cloud at +23 km s^{-1} is elongated along the northeast-southwest direction and is composed of several clumps. The clump that is spatially coincides with the PWN/IR-loop is the one in the southwestern end of the cloud. Its central velocity is 22.7 km s^{-1}, which is slightly smaller than those of the other clumps in the cloud. The median velocity of the 13CO cloud is 23.0 ± 0.2 km s^{-1}.

The morphology of the +23 km s^{-1} 12CO cloud is now understandable. At 22.5–23.1 km s^{-1}, where the cloud is most prominent, the cloud has a ‘τ’ shape, and the 13CO emission fits into the weak inner part of this structure. Therefore, the weak 12CO emission in the interior of the ‘τ’ shape should be mainly due to the absorption of the 13CO cloud. The self-absorption can be seen either when a cold CO cloud with high CO opacity but low excitation temperature is in front of warm CO gas further away, e.g., a cold cloud at 1.8 kpc aligned with a warm cloud at 8.2 kpc, or when a CO cloud has a temperature gradient along the line of sight. It is not unusual to see the self-absorption features in molecular clouds in the Galactic plane (e.g., Bieging et al. 2010). Considering the small angular sizes of the 12CO and 13CO clouds, the probability of a chance alignment of two clouds along the line of sight might be low. On the other hand, the self-absorption is prominent only to the eastern part of the 12CO cloud, which suggests that the absorbing 13CO cloud could be distinct from the 12CO cloud. This could also be due to the temperature and density structure of the cloud. To quantitatively understand the self-absorption features, one needs to solve the radiative transfer equation together with statistical rate equations, which is beyond the scope of this paper.

The PWN/IR-loop spatially coincides with the southern part of the +23 km s^{-1} cloud. There is no obvious indication of dynamical disruption in the line profile (see Fig. 8). We note that there is a wing-like structure at high velocities (23–25 km s^{-1}), which is likely due to other clouds in this area, but it needs to be confirmed with an observation of higher angular resolution. In the western part of the field, there are 12CO emissions with considerably large line widths, which are discussed in the next section.

3.4 Arc Cloud and Broad Line Molecular Gas at 15–30 km s^{-1}.

A distinct structure in the observed field is Arc Cloud seen in Fig. 2 at velocities between 15 and 23 km s^{-1} as an elongated cloud stretching over 5' along the northeast-southwest direction. Along the structure,
the $^{12}$CO line profiles have large line widths and their central velocities vary systematically as shown in Fig. 9, which shows the spectra, and Fig. 10, which is the position-velocity diagram along the arc structure. The systematic variation of the central velocity is clear; the velocity increases from 15 km s$^{-1}$ at the both ends of Arc Cloud to 23 km s$^{-1}$ at the middle point where the northern and southern arc structure merge. The velocity gradient is $\sim 8$ km s$^{-1}$ over 150$''$ from the middle to the north and south ends. At a distance of 8 kpc, it corresponds to $\sim 1.4$ km s$^{-1}$ pc$^{-1}$. The derived properties of Arc Cloud are summarized in Table 1. We choose the velocity range to be 15–22 km s$^{-1}$ to get the integrated intensity in Table 1. The range is chosen to avoid the contamination from the part of the main cloud, which start to appear at $> 22$ km s$^{-1}$ and may not belong to Arc cloud. $T_{mb}$ less than 0.4 K (several $\sigma$ level) was clipped out in the integration.

In addition to Arc Cloud, there are other broad lines at higher velocities in the northwestern area of the field. This can be seen, for example, in the line profiles of the northern part of Arc Cloud in Fig. 9. Some representative line profiles are shown in Fig. 11. In order to investigate the nature of the broad line emission, we fit the line profiles with two Gaussian components. Some profiles, i.e., the profiles with both the blue-shifted and red-shifted broad components, need three Gaussian components to describe the profiles correctly.
Nevertheless, the two-component fit should be useful to see the basic properties of the broad components. We use MPFIT, which is a least-squares fitting tool based on the Levenberg-Marquardt algorithm (Markwardt 2009). In the fit, we leave the height, central velocity, and the width of individual components free with reasonable lower and upper boundaries.

Fig. 6.— $^{12}$CO(2–1)/$^{13}$CO(1–0) ratio maps (grey scale) corresponding to the same channels in Fig. 5. The overlaid contours represent the $^{13}$CO intensities. The contours increase from 0.4 K in every 0.2 K steps.

Fig. 7.— $^{12}$CO $J = 2$–1 (solid) and $^{13}$CO $J = 1$–0 line profiles at positions where the self-absorption features are apparent. The positions of the spectra are marked in each frame with respect to (19°30'35.4'', +18°52'14'').

Fig. 8.— Average $^{12}$CO $J = 2$–1 (solid) and $^{13}$CO $J = 1$–0 line profiles toward the position of the MIR loop.

Fig. 9.— $^{12}$CO $J = 2$–1 spectra along the (a) northern and (b) southern parts of Arc Cloud at every 30° in declination. Note the broad-line component shifting systematically in velocity. Relative coordinates in arc-seconds from the map center are indicated in parentheses. The position angle in (a) is 45° at the position of the bottom spectrum. Each spectrum is plotted with 2 K temperature offset. The vertical dashed lines are drawn just for velocity reference.

Fig. 12 shows the distributions of the height, central velocity, and width of the two Gaussian components. The height map of the first (narrow) component shows the morphology of the 23 km s$^{-1}$ component nicely. The second component represents the broad-line component, and its maps show that the broad-line component is confined to the western part of the field. In the

The southern part is brighter and more compact than the northern part.

central velocity map, we can identify Arc Cloud, which has a velocity gradient that we described above. The broad lines at higher velocities appear mainly on the western side of Arc Cloud. The very large width at the tip of the arc-like cloud indicates that, at those pixels, both blue-shifted and red-shifted velocity components appear (see Fig. 11). Fig. 13 plots the line width versus central velocity of the two Gaussian components. The black dots confined to the central velocity of 23 km s\(^{-1}\) and a width (FWHM) of 1.4 km s\(^{-1}\) represents the first Gaussian component, or the +23 km s\(^{-1}\) cloud component. The red dots represent the second Gaussian component, or the broad component, and they are scattered over the plane. The points with central velocities less than 20 km s\(^{-1}\) might be from Arc Cloud, while the points with widths greater than 7–8 km s\(^{-1}\) have both red-shifted and blue-shifted broad components. Fig. 13 shows that the broad lines in the western part of Arc Cloud have central velocities of 20–26 km s\(^{-1}\) and widths of 2–7 km s\(^{-1}\).

spatial correlation with the PWN, which led them to propose the association although there is no direct evidence for the interaction. Our 12CO \(J = 2–1\) map confirms the spatial correlation. The +23 km s\(^{-1}\) component spatially coincides with the IR shell while the 53 km s\(^{-1}\) component appears to be in contact with the eastern boundary of the PWN. The kinematic distances to these clouds are 1.8/8.2 kpc and 6.9 kpc, respectively. The distance to G54.1+0.3 has previously been determined in several studies. The distance based on HI absorption spectrum is from 5 to 10 kpc (Koo et al. 2008; Leahy et al. 2008), and the free-electron density/distance model (Cordes & Lazio 2002) gives the distance of 9–15 kpc to the PSR J1930+1852 at the center of the PWN from its dispersion measure (Camilo
Recently, Kim et al. (2012) derived a distance of $6.0 \pm 0.4$ kpc to the IR-excess stellar objects from a spectro-photometric study. Therefore, the estimated distance to the SNR ranges from 5 to 9 kpc, and in principle either of the cloud can be associated with the SNR.

The +53 km s$^{-1}$ cloud is composed of several arc-minute-sized clumps forming a kink-shaped structure (Fig. 3). The PWN is located in the middle where the cloud appears to kink. While the spatial correlation is suggestive for the interaction as pointed out by Leahy et al. (2008), we do not see any direct evidence of the interaction as its $^{12}$CO $J = 2-1$ line profiles are well described by a single Gaussian with velocity widths (FWHM) of 1.5–2.0 km s$^{-1}$. It is difficult to imagine a molecular cloud right at the SN explosion site but not disrupted. Also, the PWN shows no indication that it has encountered a dense medium only in the east as its radio structure has east-west symmetry. Therefore, we consider that the association of the +53 km s$^{-1}$ cloud with the PWN is not likely. There is weak ($\sim 1$ K) diffuse emission with broad lines at comparable velocities in the eastern area of the cloud. The association of this diffuse component with the +53 km s$^{-1}$ cloud is uncertain. However, since it extends beyond the radio boundary of the SNR, it is not likely that this component is associated with the SNR.

The 23 km s$^{-1}$ cloud has a complex structure with pronounced self-absorption features. The self-absorption could be either due to a foreground cold CO cloud along the line of sight or due to a temperature gradient in the cloud. The entire cloud structure is large ($\sim 10'$) and again it is not likely that this cloud is associated with the SNR. There is a small clump in the southwestern end of the cloud that coincides with the MIR loop (Koo et al. 2008) at $\sim 22$ km s$^{-1}$ (see Fig. 5). It is not impossible that this clump is spatially separate from the +23 km s$^{-1}$ cloud, but there is no obvious indication of dynamical disruption in its line profile.

A distinct structure detected in this study is Arc Cloud in the west of the PWN at velocities between 15 and 23 km s$^{-1}$. The cloud is 5' long and has a large line width. The central velocity increases from both ends of the cloud to the middle point systematically. The velocity at the end of the arc cloud is 15 km s$^{-1}$, so that the velocity shift from the middle (+23 km s$^{-1}$) is $\sim 8$ km s$^{-1}$. There are also other broad lines at higher velocities in the west of Arc Cloud. The association of this broad line emission with Arc Cloud is possible. It is interesting to note that the radio brightness of the SNR is relatively faint in its western part, where the arc-like cloud and the broad-line clouds are located (see Fig. 4 of Lang et al. 2010). The SNR shock of G54.1+0.3 is currently expanding at $\sim 2,000$ km s$^{-1}$ and the density of the ambient medium is $\sim 0.2$ cm$^{-3}$ (Bocchio et al. 2010). If a dense molecular cloud is swept-up by
this shock wave, the shock speed drops by the square root of the density contrast. Therefore, Arc Cloud and the broad-line cloud could have been produced by the SNR shock if they were recently swept-up and if their densities were \( \sim 10^4 \) cm\(^{-3} \). In this part of the sky, however, there is a large star-forming molecular cloud near the Galactic plane with the same LSR velocity at a distance of 2 kpc. It is possible that the cloud we observe is a part of this cloud system. A further study is required to investigate their association.

In conclusion, we have not detected any direct evidence for the interaction of either the +53 or +23 km s\(^{-1} \) cloud with the SNR from our CO J = 2–1 line observations. However, we have detected molecular gas with broad lines and systematic velocity structure at \( \nu_{\text{LSR}} = 15–30 \) km s\(^{-1} \) to the west of the IR loop inside the SNR. Their association with the SNR needs to be investigated with further observations.
