ABSTRACT

The core and global properties of the early-type (“red sequence”) galaxies in the Virgo and Fornax clusters are examined using high-quality HST/ACS imaging for 143 galaxies. Rather than dividing neatly into disparate populations having distinct formation and/or evolution histories, many of the core and global properties of these galaxies show smooth and systematic variations along the galaxy luminosity function. The few examples of the rare class of compact elliptical galaxies in our sample all show properties that are strongly suggestive of tidal stripping by massive galaxies; if so, then these systems should not be viewed as populating the low-luminosity extension of so-called “normal” elliptical sequences. These results demonstrate that complete and/or unbiased samples are a pre-requisite for identifying the physical mechanisms that gave rise to the early-type galaxies we observe locally, and how these mechanisms varied with mass and environment.

key words: galaxies: clusters: individual: name: Virgo; galaxies: elliptical and lenticular, cD; galaxies: nuclei; galaxies: star clusters

1. INTRODUCTION

An understanding of the physical processes that shaped the structure of galaxies we observe locally is a key goal of modern astrophysics. This goal, however, has proved challenging for early-type galaxies which are historically believed to exhibit puzzling structural “dichotomies” that suggest sharply disjointed formation processes. For instance, bright elliptical galaxies have been reported to divide — at roughly $M_B \approx -20.5$, corresponding to a stellar mass of $M_\star \approx 2 \times 10^{11} M_\odot$ — into two distinct populations based on the logarithmic slope of their central surface brightness profiles (i.e., the “core/power - law dichotomy”; e.g., Ferrarese et al., 1994; Lauer et al., 1995). This apparent dichotomy has been interpreted as evidence for two distinct galaxy populations whose core properties are thought to result from either supermassive binary black hole evolution (“core” galaxies) or gas dissipation (“power-law” galaxies).

Meanwhile, at somewhat lower luminosities and masses (i.e., $M_B \approx -17.5$ and $M_\star \approx 6 \times 10^9 M_\odot$), an abrupt change in central and global structure has been claimed to separate “normal” ellipticals (comprised of both “core” and “power-law” galaxies) from low-luminosity “dwarf” or “spheroidal” systems (e.g., Kormendy, 1985). It should be noted, however, that several subsequent studies have questioned the existence of both dichotomies, finding that at least some galaxies with intermediate properties may bridge the respective gaps (e.g., Jerjen & Binggeli, 1997; Rest et al., 2001; Ravindranath et al., 2001; Graham et al., 2003; Graham & Guzmán, 2003; Gavazzi et al., 2005).

2. SAMPLE SELECTION AND ANALYSIS

The ACS Virgo (Côté et al., 2004) and Fornax (Jordán et al., 2007a) Cluster Surveys are large HST imaging programs that were carried out, in part, to characterize these structural dichotomies using high-resolution, multi-color, homogeneous imaging for a carefully se-
Fig 1.— Mosaic showing the 100 galaxies observed in the ACS Virgo Cluster Survey. These galaxies constitute a complete sample of early-type systems in the Virgo Cluster brighter than $M_B \approx -19$, and an unbiased sample of 54% of all Virgo early types down to $M_B \approx -15$. The corresponding sample in the Fornax Cluster is complete down to $M_B \approx -16.1$.

Selected sample of early-type galaxies belonging to the two galaxy clusters nearest to the Milky Way (see Figure 1). In order to shed light on the dichotomies mentioned above, the central and global properties of early-type galaxies (e.g., E, S0, E/S0, S0/E, or their “dwarf” counterparts; Binggeli et al., 1985; Ferguson, 1989) were derived simultaneously by parameterizing the surface brightness profiles — derived from ACS imaging and supplemented with ground-based photometry from the literature or from SDSS — with the family of Sérsic models (e.g., Sérsic, 1968; Caon et al., 1993, 1994; Graham et al., 2003). A secondary goal of the surveys (see §3.3) was to characterize the properties of globular cluster systems for a large sample of early-type galaxies that span a wide range in galaxy luminosity and mass, thereby extending pioneering HST archival studies of globular clusters in early-type environments (Gebhardt & Kissler-Patig, 1999; Kundu & Whitmore, 2001; Larsen et al., 2001).

At this point, a word on the sample selection is in order. In many past studies, galaxies were selected on the basis of morphology (e.g., choosing pure samples of Es, S0s, or dwarfs — often by relying on morphological classifications from early photographic resources such as the RC3). Since our comparison of morphological classifications for Virgo and Fornax galaxies taken from various sources often showed poor agreement — particularly at intermediate luminosities where the distinction between E and S0s (see also Emsellem et al., 2007) and between “giants” and “dwarfs” is not always obvious from visual inspection — it was decided to focus on the ensemble of early type galaxies. As Figure 2 shows, this broad morphological selection effectively isolates those galaxies that define the local “red sequence” in the color-magnitude diagrams of these two clusters. Thus, the sample selection used here roughly mirrors the one that is widely used in the study of much...
more distant galaxy populations.

3. RESULTS

3.1. Central Surface Brightness Profiles: From a Luminosity “Deficit” to “Excess”

Figure 3 shows that the azimuthally-averaged surface brightness profiles of early-type galaxies can be parameterized accurately over a wide range in radius (≥ 3 decades) by Sérsic (1968) models (see Ferrarese et al., 2006a, b; Côté et al., 2006, and earlier studies by Caon et al., 1993, 1994; Jerjen & Binggeli, 1997; Graham & Guzman, 2003; Gavazzi et al., 2005). This applies not just to luminous “giants” (with Sérsic indices of n ~ 4) and faint “dwarfs” (n ~ 1), but also to galaxies with intermediate luminosities.

An important qualification is that there are systematic deviations in the innermost regions (R ≤ 0.02 R_e) of most galaxies. Those brighter than M_B ~ −20.5 (M_∗ ~ 10^{11} M_☉) show central luminosity deficits with respect to inward extrapolations of Sérsic models, possibly due to core evacuation caused by coalescing black hole binaries (e.g. Ebisuzaki et al., 1991; Faber et al., 1997; Milosavljević & Merritt, 2001). By contrast, galaxies fainter than M_B ~ −19.5 (M_∗ ~ 10^{10.6} M_☉) usually show central luminosity excesses, or nuclei (Ferrarese et al., 2006b; Côté et al., 2006)\(^2\) that may in some cases be the signature of star formation resulting from gas inflows during mergers or accretions (Mihos & Hernquist, 1994; Côté et al., 2007; Hopkins et al., 2009; Kormendy et al., 2009), although other processes,

\(^2\)This result has recently been confirmed by Kormendy et al. (2009), who re-analyzed a subset (40/100) of the ACS Virgo Cluster Survey galaxies.
such as nucleus growth from globular clusters that have been drawn to the galaxy center by dynamical friction (Tremaine et al., 1975), may also play a role. In any case, these deviations typically amount to less than one percent of the total galaxy luminosity and they are confined to within $\sim 1\%$ of the radial range over which Sérsic models fit with high accuracy. Thus, these central deviations do not influence the global structural parameters.

3.2. Global Properties

Figure 4 confirms that, although the global properties of the galaxies do indeed vary along the luminosity function, they do not do divide into discrete, mutually exclusive populations. For instance, the left panels of this figure plot the variation with absolute magnitude of several basic global parameters: mean ellipticity, mean isophote shape, $g$-band surface brightness measured at a fixed physical scale of 400 pc, mean $(g-z)$ color, and velocity dispersion measured inside $R_e/8$. The smooth curves drawn in each panel show low-order polynomial fits, illustrating the continuities along the luminosity function. This exercise demonstrates the importance of sample selection: i.e., had one simply selected samples of bright (“normal”) ellipticals and faint (“dwarf”) galaxies, it would be tempting to conclude that the two samples are fundamentally distinct in their properties.

3.3. Globular Cluster Properties Along the Luminosity Function

As mentioned in §1, a second motivation of the ACS Virgo and Fornax Cluster Surveys was a characterization of the properties of globular clusters in early-type galaxies. The right panels of Figure 4 show the variation along the galaxy luminosity function of several important observables for the globular clusters in these galaxies, taken from the studies of Jordán et al. (2005, 2007b), Peng et al. (2006, 2008), Villegas et al. (2010) and Masters et al. (2010). From top to bottom, these panels show the mean globular cluster color, specific frequency, mean half-light radius, and the “turnover” magnitude and dispersion of the globular cluster luminosity function. In almost every case, there is a gradual and systematic variation along the red sequence luminosity function, contrary to what would be expected if there were sharp discontinuities in the physical processes that shaped these galaxies.

3.4. The Case of the Compact Ellipticals

Although Figures 2 and 4 show smooth trends from the brightest elliptical galaxies down to the regime of “dwarf” galaxies (i.e., those systems usually denoted by the dE, dS0, dSph or Sph nomenclature), there is a handful of galaxies that do seem to depart from the sequences defined by the majority of early-type galaxies. These four galaxies, which are plotted in red in both figures, are examples of the rare class of “compact ellipticals”.

Like M32, the proto-type for this class, each of these galaxies is found close to a much more massive companion. Moreover, all have some unusual properties that are qualitatively consistent with those expected for objects that have undergone substantial tidal stripping (Faber, 1973; Bekki et al., 2001; Chilingarian et al., 2009): e.g., compact size, high surface brightness, unusually red color and reduced GC specific frequency. These results suggest that compact ellipticals like M32 should not be viewed as low-luminosity analogs of “giant E” galaxies, as has sometimes been claimed (e.g., Kormendy, 1985; Kormendy et al., 2009), but, rather, as unusual objects whose extreme properties are the signature of an atypical formation channel, in which one of the many physical processes (e.g., merging, stripping, harassment, dissipation, etc.) acting on galaxies has been dominant in their evolution (Chilingarian et al., 2009; Price et al., 2009). This interpretation would be consistent with the observation of Bender et al. (1992) that: “The rarity of such galaxies [cEs] suggests that this does not happen often during galaxy formation.”

4. DIRECTIONS FOR FUTURE RESEARCH

A number of conclusions can be drawn from the above discussion. First, the importance of a well-defined, objective galaxy selection function can scarcely be overestimated; while morphology will always play a role in the study of galaxy evolution, it seems preferable in the future to use quantitative selection criteria (such as location in the galaxy color-magnitude diagram; see Figure 2) to isolate complete and/or unbiased samples that can be then used to determine what morphology may be telling us about the relative balance of the physical properties driving galaxy evolution, rather than the other way around. Second, it will be important to extend the imaging surveys described here to lower masses and bluer colors (= later types) with high lev-
Two large imaging surveys are now underway that should provide important steps forward in this area: (1) the ACS Coma Cluster Survey on HST (PI = Carter) and; (2) the Next Generation Virgo Cluster Survey on CFHT (PI = Ferrarese). The latter survey, which should be completed in 2012, is currently surveying the entire Virgo Cluster in $ugiz$ down to a point-source depth of $g_{AB} \simeq 25.7 (10\sigma)$. It will enable a more complete characterization of galaxy scaling relations — as well as those of their globular cluster systems — from the level of brightest cluster members down to dwarf galaxies with luminosities approaching those of Galactic dSphs.

**ACKNOWLEDGEMENTS**

I thank my collaborators from the ACS Virgo and Fornax Surveys for allowing me to present some results in advance of publication, and Profs. Sukyoung Yi and Suk-Jin Yoon for their extraordinary hospitality during this superb workshop.
