Application of Opposition-based Differential Evolution Algorithm to Generation Expansion Planning Problem

K. Karthikeyan†, S. Kannan*, S. Baskar** and C. Thangaraj***

Abstract – Generation Expansion Planning (GEP) is one of the most important decision-making activities in electric utilities. Least-cost GEP is to determine the minimum-cost capacity addition plan (i.e., the type and number of candidate plants) that meets forecasted demand within a pre specified reliability criterion over a planning horizon. In this paper, Differential Evolution (DE), and Opposition-based Differential Evolution (ODE) algorithms have been applied to the GEP problem. The original GEP problem has been modified by incorporating Virtual Mapping Procedure (VMP). The GEP problem of a synthetic test systems for 6-year, 14-year and 24-year planning horizons having five types of candidate units have been considered. The results have been compared with Dynamic Programming (DP) method. The ODE performs well and converges faster than DE.

Keywords: Dynamic programming, Differential evolution, Generation expansion planning, Opposition-based differential evolution, Virtual mapping procedure

1. Introduction

The Generation Expansion Planning (GEP) problem for an electric utility is the problem of determining WHAT generation plants should be constructed, WHERE and WHEN they should be committed over a “long-range” planning horizon [1-2]. GEP is a challenging problem due to its non-linear, large-scale, highly constrained, and discrete nature of the decision variables (unit size and allocation) [2-3].

The basic objective of the GEP is to determine the best investment plan that minimizes present value of the investment and operating costs such that it will meet the load demand. Earlier for finding the solution of the GEP problem, the methods like DP [3], tunnel constrained DP [4], Branch and bound method [5], and Benders-decomposition [6] were applied. Some of the emerging techniques for GEP problem are reviewed in [7].

Genetic Algorithm (GA) and its variants are applied to the GEP in [8-10]. Argyris G Kagiannas et al have given a comprehensive review of GEP methods applied from monopoly to Competitive markets [11]. Hybrid approaches like GA with Immune algorithm [12] and DP [13] are also applied. Eight meta-heuristic techniques were applied and the results are compared with DP in [14]. The authors concluded that Differential Evolution (DE) [15] outperformed other meta-heuristic techniques.

The Elitist Non-dominated Sorting Genetic Algorithm version II (NSGA-II) is applied to multi-objective GEP problem [16-17]. The environmental constraints and impact of various incentive mechanisms are considered in [18-20]. Yanyi He et al compared the effectiveness and efficiency of cap-and-trade and carbon tax policies in a GEP framework [21].

The game theory and modified game theory along with Meta-heuristic techniques has been applied to GEP in partially deregulated and Competitive environment in [22-26]. Still in the developing countries, the GEP has been done by the Centralized Electricity Authority. Hence, the least cost GEP model will be very much useful for those countries.

DE has been widely applied in variety of fields [27-28]. Even though it produces better results, the convergence rate of the DE for a particular problem is low. The concept of Opposition-based Learning has been utilized to accelerate the convergence rate of DE in [29]. This new approach has been called as opposition-based differential evolution (ODE) [30].

In this paper, DE, and ODE are applied to the GEP problem and the results are compared with DP. The rest of the paper is organized as follows: Section II describes the GEP problem formulation and Section III describes implementation of the GEP problem. Section IV provides test results, and section V concludes.
decision vectors over a planning horizon that minimizes the investment and operating costs under relevant constraints.

2.1. Cost objective

The cost objective is represented by the following expression

\[
\min \text{Cost} = \sum_{t=1}^{T} \left[ I(U_t) + M(X_t) + O(X_t) - S(U_t) \right] \tag{1}
\]

where,

\[
X_t = X_{t,0} + U_t \quad (t = 1,2,\ldots,T) \tag{2}
\]

\[
I(U_t) = (1 + d)^{s'} \sum_{j=1}^{N} \left( CI \times U_{t,j} \right) \tag{3}
\]

\[
S(U_t) = (1 + d)^{s'} \sum_{j=1}^{N} \left( CI \times \delta_i \times U_{t,j} \right) \tag{4}
\]

\[
M(X_t) = \sum_{s=0}^{1} \left[ (1 + d)^{1.5-s'} \left( \sum_{i=1}^{N} (X_i \times FC) + MC \right) \right] \tag{5}
\]

\[
O(X_t) = \text{EENS} \times \text{OC} \times \sum_{s=0}^{1} \left( (1 + d)^{1.5-s'} \right) \tag{6}
\]

The outage cost calculation of (6), used in (1), depends on Expected Energy Not Served (EENS). The equivalent energy function method [1] is used to calculate EENS (and also to calculate loss of load probability, LOLP, used in the constraint objective).

\[
t' = 2(t-1) \quad \text{and} \quad T' = 2 \times T - t' \tag{7}
\]

\[\text{Cost} \quad \text{total cost, } \text{S};\]

\[U_t \quad \text{N-dimensional vector of introduced units in the } t\text{-th stage (1 stage = 2 years)};\]

\[U_{t,j} \quad \text{the number of introduced units of } i\text{-th type in } t\text{-th stage};\]

\[X_t \quad \text{cumulative capacity vector of existing units in } t\text{-th stage, (MW)};\]

\[I(U_t) \quad \text{is the investment cost of the introduced unit at the } t\text{-th stage, } \text{S};\]

\[M(X_t) \quad \text{total operation and maintenance cost of existing and the newly introduced units, } \text{S};\]

\[s' \quad \text{variable used to indicate that the maintenance cost is calculated at the middle of each year};\]

\[O(X_t) \quad \text{outage cost of the existing and the introduced units, } \text{S};\]

\[S(U_t) \quad \text{salvage value of the introduced unit at } t\text{-th interval, } \text{S};\]

\[d \quad \text{discount rate};\]

\[C_l \quad \text{capital investment cost of } i\text{-th unit, } \text{S};\]

\[\delta_i \quad \text{salvage factor of } i\text{-th unit};\]

\[T \quad \text{length of the planning horizon (in stages)};\]

\[N \quad \text{total number of different types of units};\]

\[FC \quad \text{fixed operation and maintenance cost of the units, } S/MW;\]

\[MC \quad \text{variable operation and maintenance cost of the units, } S;\]

\[\text{EENS} \quad \text{Expected energy not served, } \text{MWhrs};\]

\[\text{OC} \quad \text{value of outage cost constant, } S'/\text{MWhrs}\]

2.2. Constraints

1) Construction limit: Let \(U_t\) represent the units to be committed in the expansion plan at stage \(t\) that must satisfy

\[
0 \leq U_t \leq U_{\text{max},t} \tag{8}
\]

where \(U_{\text{max},t}\) is the maximum construction capacity of the units at stage \(t\).

2) Reserve Margin: The selected units must satisfy the minimum and maximum reserve margin.

\[
(1 + R_{\text{max}}) \times D_t \leq \sum_{j=1}^{N} X_{t,j} \leq (1 + R_{\text{min}}) \times D_t \tag{9}
\]

where

\[R_{\text{min}} \quad \text{minimum reserve margin};\]

\[R_{\text{max}} \quad \text{maximum reserve margin};\]

\[D_t \quad \text{demand at the } t\text{-th stage in megawatts (MW)};\]

\[X_{t,j} \quad \text{cumulative capacity of } i\text{-th unit at stage } t.\]

3) Fuel Mix Ratio: The GEP has different types of generating units such as coal, liquefied natural gas (LNG), oil, and nuclear. The selected units along with the existing units of each type must satisfy the fuel mix ratio

\[
F_{\text{min}}^j \leq \frac{1}{N} \sum_{i=1}^{N} X_{i,j} \leq F_{\text{max}}^j \quad j = 1, 2, \ldots, N \tag{10}
\]

where

\[F_{\text{min}}^j \quad \text{minimum fuel mix ratio of } j\text{-th type};\]

\[F_{\text{max}}^j \quad \text{maximum fuel mix ratio of } j\text{-th type};\]

\[j \quad \text{type of the unit (e.g., oil, LNG, coal, nuclear)}.\]

4) Reliability Criterion: The introduced units along with the existing units must satisfy a reliability criterion on loss of load probability (LOLP)

\[
\text{LOLP}(X_t) \leq \varepsilon \tag{11}
\]

where \(\varepsilon\) is the reliability criterion, a fraction, for maximum allowable LOLP. Minimum reserve margin constraint avoids the need for a separate demand constraint.
3. Implementation of the GEP Problem

3.1. Virtual Mapping Procedure (VMP)

To improve the convergence characteristics of the algorithms, VMP is introduced in the GEP problem. VMP is concerned with the solution representation; it transforms each combination of candidate units for every year into a dummy decision variable, referred to as the VMP variable [14]. The value of the VMP variable for a specific candidate solution is the rank of that solution when all solutions are sorted in ascending order of capacity.

To illustrate, consider the range of the decision vector lies between [0] and \( U_{\text{max}} \) as given in [9]. The capacity vector is \([200 450 500 1000 700]\). Let a candidate solution be \( U_1 = [0 1 1 0 0] \); then its corresponding capacity will be 2500 MW (5x200 + 0x450 + 1x500 + 1x1000 + 0x700). If \( U_i \) changes to \([0 1 2 0 2]\) (via mutation operators), then the capacity is increased from 2500 MW to 3500 MW, a difference of 1000 MW, which is a large deviation.

The solution \([5 0 1 1 0]\) with capacity of 2500 has VMP value of 190. A change (by mutation) to VMP value of 198 would correspond to a solution of \([2 1 2 0 1]\) with capacity of 2550, a relatively small change in capacity. Without VMP, to get a solution with capacity of 2550, all 5 variable values must be changed. This may take a very large number of iterations, and in general, moving from sub-optimal to optimal may take much iteration.

Since five different types of units are assumed to be available for each stage, the size of the decision vector increases by multiples of 5 as the number of stages increases. However, when using VMP, the number of decision variables obtained is a multiple of its number of stages; the size of the decision vector becomes 3 for a 3-stage problem. Thus, a size reduction of 80%, \([15-3]/15\), for 3 stages] is realized. Hence, the dimensionality of the problem, in terms of the number of decision variables, is reduced, and computational time and memory requirements reduce accordingly.

3.2. Differential Evolution (DE)

Price and Storn [15] proposed DE. It is a population-based stochastic direct search algorithm like GA but differs from GA with respect to the mechanics of mutation, crossover, and selection.

At each iteration \( J \), DE employs the mutation and crossover operations to produce a trial vector \( V_{i,J} \) for each individual vector \( X_{i,J} \), also called target vector, in the current population.

Based on the mutation rule, the DE has been classified into more than ten different strategies [15]. Few of them are:

i) DE/best/1

\[
U_{i,J+1} = X_{\text{best}} + F \times (X_{n-i,J} - X_{n-2,J})
\]

ii) DE/rand/1

\[
U_{i,J+1} = X_{r,J} + F \times (X_{n-i,J} - X_{n-2,J})
\]

iii) DE/rand-to-best/1

\[
U_{i,J+1} = X_{\text{best}} + F \times (X_{n-i,J} - X_{n-2,J} - X_{n-1,J})
\]

iv) DE/best/2

\[
U_{i,J+1} = X_{\text{best}} + F \times (X_{n-i,J} - X_{n-2,J} - X_{n-1,J} - X_{n-3,J})
\]

v) DE/rand/2

\[
U_{i,J+1} = X_{r,J} + F \times (X_{n-i,J} - X_{n-2,J} - X_{n-1,J} - X_{n-3,J})
\]

where,

- \( X \) is the set of population
- \( U_{i,J+1} \) is the mutated \( i \)-th individual for the next iteration
- \( X_{i,J} \) is \( i \)-th individual of current iteration
- \( X_{\text{best}} \) is the best individuals among the population
- \( F \) is a constant \([0, 2]\)
- \( J \) is the current iteration
- \( X_{1,J}, X_{2,J}, X_{3,J}, X_{4,J}, \) and \( X_{5,J} \) are the randomly selected populations in the current iteration.

After mutation, the exponential crossover is applied on the individuals by the rule

\[
V_{i,J+1} = \begin{cases} 
U_{i,J+1} & \text{if } \text{rand} \leq CR \text{ or } k = k_{\text{rand}} \\
X_{i,J} & \text{otherwise , } k = 1,2,...,n 
\end{cases}
\]

where, \( CR \) is the crossover rate \([0, 1]\)

The parents for the next iteration are selected based on one-to-one greedy selection scheme for minimization problems such as GEP as follows:

\[
X_{i,J+1} = \begin{cases} 
V_{i,J+1} & \text{if } f(V_{i,J+1}) > f(X_{i,J+1}) \\
X_{i,J+1} & \text{if } f(X_{i,J+1}) > f(V_{i,J+1}) 
\end{cases}
\]

where,

\( f(V_{i,J+1}) \) is the fitness function value of \( i \)-th individual of the population in which the mutation and crossover operators are applied

\( f(X_{i,J+1}) \) is the fitness function value of \( i \)-th individual in the original population

The loss of best individuals in the subsequent iteration is avoided by this selection mechanism, as the best individuals replace the worst individuals.

3.3. Opposition-based Differential Evolution (ODE)

ODE [24] uses opposite numbers during population initialization and also for generating new populations.
during the evolutionary process. The main idea behind the opposition is the simultaneous consideration of an estimate and its corresponding opposite estimate (i.e., guess and opposite guess) in order to achieve a better approximation for the current candidate solution. The pseudo code for the ODE [25] is given below

1: Generate uniformly distributed random population $X_0$
   /*Opposition-based Population Initialization*/
2: for $i = 0$ to $NP$ do
3:   for $j = 0$ to $D$ do
4:     $OX_{0i,j} ← X_{min,j} + X_{max,j} − X_{0i,j}$
5:   end for
6: end for
7: Select $NP$ fittest individuals from set the $\{X_0, OX_0\}$ as initial population $X_0$
   /*Opposition-based Population Initialization*/
8: while ($J < J_{max}$ and $NFE < MAXNFE$) do /*NFE number of function evaluations*/
9:   DE's Evolution steps
   /*Opposition-based Generation Jumping*/
10: if $rand(0, 1) < Z_r$ (Jumping rate) then
11:     for $i = 0$ to $NP$ do
12:       for $j = 0$ to $D$ do
13:         $OX_{i,j} ← \text{MIN}^j + \text{MAX}^j - X_{i,j}$
14:       end for
15:     end for
16: Select $NP$ fittest individuals from set the $\{X, OX\}$ as current population $X$
17: end if
   /*Opposition-based Generation Jumping*/
18: end while

4. Test Results

All the algorithms DE, ODE, and DP were implemented using MATLAB version 7.2, on a desktop PC with Intel Core i5 processor having 3.10GHz speed and 4 GB RAM.

4.1. Test system description

The forecasted peak demand and other technical data are taken from [9]. The test system with 15 existing power plants and 5 types of candidate options is considered for a 6-years, 14-years and 24-years planning horizon. The planning horizon comprises of stages with 2-year intervals.

4.2. Parameters for GEP

The lower and upper bounds for reserve margin are set at 20% and 40% respectively. The salvage factor ($\delta$) for oil, LNG, coal, PWR, and PHWR are taken as 0.1, 0.1, 0.15, 0.2 and 0.2, respectively. Cost of EENS is set at 0.05 $/kWh. The discount rate is 8.5%. It is assumed that the date of availability of new generation is two years beyond the current date. The year $k$ investment cost is assumed to incur in the beginning of year $k$; the year $k$ maintenance cost is assumed to incur in the middle of year $k$ and is calculated by using the equivalent energy function method [1]. The year $k$ salvage cost is estimated at the end of the planning horizon.

4.3. Parameters for DE, and ODE

The best parameters for the algorithms DE, and ODE are chosen through 50 independent test runs. Their values for the entire planning horizon are tabulated in Table 1. These values are taken for all the experiments conducted; a change is mentioned in a parameter when we want to study the impact of that particular parameter on GEP problem.

4.3. Results and discussion

The effect of population size, mutation strategy, jumping rate, virtual mapping procedure and selection mechanism are investigated and results for all the planning horizons are presented in this section.

1. Effect of Population Size

In order to investigate the effect of the population size, experiments with various population sizes are done and the results are reported in Table 2. The 6-year planning horizon is considered, since it consumes lesser computational time rather than higher planning horizon. Here the DE and ODE...
are considered with VMP.

The solution obtained by the DP is the optimal solution and it is taken as the reference for calculating the error percentage. The Success Rate (SR) is the ratio of the number of times the optimal solution found to the number of test runs. According to the results, the ODE performs better than DE. For larger population size 60, both the DE and ODE produces the better results i.e., 100% SR.

2. Effect of Various Mutation Strategies

There are more than ten mutation strategies are available for the DE. Many of the works reported in [15, 27, 28], utilizes the standard one, DE/rand/1/bin. We also utilized the same strategy for our GEP problem. In order to validate our choice we did some experiments with three other well known mutation strategies, DE/rand/1/exp, DE/rand/2/exp, and DE/rand/2/bin. The results are presented in Table 3.

According to the results in Table 3, the best mutation strategy for the both DE and ODE is DE/rand/1/bin.

3. Effect of Jumping Rate ($Z_r$)

In ODE, there is a new parameter called Jumping rate $Z_r$, that has to be fixed for the entire planning horizon. Obviously, the performance of the ODE will vary according to this parameter. If $Z_r=0$, means that there is no jumping at all, on the other hand if $Z_r=1$ in all the iterations jumping will take place and hence the number of function evaluations will increase. According to [29, 30] larger jumping rate more than 0.6 will lead the algorithm to premature convergence for most of the problem. The various values are taken for the comparison and the results are given in Table 4.

The other parameters, namely maximum number of function evaluations, cross over rate (CR) and scaling factor ($F$) are shown in Table 1 is also calculated based on the same type of experiments. The maximum number of function evaluations in ODE includes the extra evaluations required for the opposite points both at population initialization and generation jumping.

4. Effect of Virtual Mapping Procedure (VMP)

The results for the 6 year planning horizon for DE and ODE with and without VMP are presented in Table 5. The performance of the DE and ODE without VMP is poor, since it is not able to produce the 100% SR. Both DE and ODE with VMP are performing better, and hence it is very clear that inclusion of VMP improves the SR and also the performance of the algorithms. The convergence characteristics of DE and ODE with VMP are shown in Fig. 1 (only 150 iterations are shown for better clarity). The ODE converges faster than DE and also variations in cost during iterations are lower in ODE than DE. The results of the GA and PSO [14] have also been given in Table 5 for comparison purpose. The DE and ODE results are better than GA and PSO, in terms of error and SR.

5. Effect of Selection Mechanism

In ODE algorithm, the best individuals based on the fitness value (objective function value) are selected during the population initialization and generation jumping. Since GEP is constrained problem; the best fit individual may have the constraint violation. Hence, in our study tournament selection with the pair-wise comparison is used. The individuals are selected based on the following procedure

- when both individual and its opposite are feasible, the one with better objective function value is chosen,
- when individual is feasible and its opposite is infeasible, the feasible solution is chosen, and vice-versa
- when both individual and its opposite are infeasible, the one with smaller constraint violation is chosen.

![Fig. 1. Convergence Characteristics of DE and ODE for 6-year planning horizon](image-url)
For the 6-year planning horizon, both the selection mechanism produces the 100% SR, hence the results for the 14-year planning horizon is taken for comparison purpose and presented in Table 6.

The error rate for ODE is lesser than the DE both in best cost and worst cost values. That means ODE better converges to the near optimal solution rather than DE. If we replace the selection with tournament selection, the number of times getting the best value is increases. Obviously the mean execution time is increased for the extra computational time required for the comparison.

6. Results for the 24 Year Planning Horizon

The optimal solution (through DP) for the 24 year planning horizon is unknown; it is very difficult to calculate the value due the high time complexity of the problem. The time required to solve the GEP problem increases exponentially with increase in planning period. It is clear from the Table 5 and Table 6 that the mean execution time required for the 14 year planning horizon through DP is 282.81 times higher than mean execution time required for the 6 year planning horizon. Projecting the same for 24 year planning horizon, it may be required to run the DP program continuously for 6 days (approximate), which is impractical.

In [14], it is given that for 24-year planning horizon the best cost value is $2.9206 \times 10^{10}$. ODE provides better result than that with lesser computational time.

5. Conclusion

The Differential Evolution (DE) and Opposition-based Differential Evolution (ODE) have been applied to solve the GEP problem. The optimal solution or near optimal solution is obtained by incorporating VMP. The results were validated with DP. The performance of the DE and ODE are compared in terms of their success rate and error percentage. For the shorter planning horizon (6-year), both DE and ODE are able to find the optimal solution. For the longer planning horizon (14-year), and very long planning horizon (24-year), ODE performs very well and produces better results than DE. The effects of population size, Mutation Strategies, VMP, Jumping rate and Selection Mechanism are also studied on the performance of DE and ODE algorithms. The results are also compared with GA and PSO results which are available in the literature.

Acknowledgments

The authors gratefully acknowledge the management of Kalasalingam University, Krishnanokil and Thiagarajar College of Engineering, Madurai for their constant support and encouragement extended during this research. They are also thankful to the Department of Science and Technology, New Delhi, for its support through the project: SR/S4/ MS/364/06.

K. Karthikeyan received the B. E. Degree from Madurai Kamaraj University in 2002, and M.E Degree from Jadavpur University, Kolkata in 2007. He is pursuing his Ph.D. in Kalasalingam University. His field of interest is Generation Expansion Planning and Evolutionary Computation. He is a Member of IEEE and Life Member of ISTE, SSoI and IAEng.

S. Kannan received the B.E., M.E., and Ph.D. Degrees from Madurai Kamaraj University, Madurai, India in 1991, 1998 and 2005 respectively. He was a visiting scholar at Iowa State University, Ames, from October 2006 to September 2007, supported by the DST, Government of India, with the BOYSCAST Fellowship. His field of interest is power system planning, multi-objective optimization and evolutionary computation. He is a Life member of SSoI and ISTE, Senior member of IEEE and IETE.

S. Baskar received the B.E. and the PhD degrees from Madurai Kamaraj University, Madurai, India, in 1991 and 2001, respectively, and the M.E. degree from Anna University, India, in 1993. He did his post-doc research in Evolutionary optimization at NTU, Singapore. Prof. S. Baskar is a senior member of IEEE, Fellow of IE(I) and Life Member of the ISTE. He was the recipient of the Young Scientists BOYSCAST Fellowship during 2003–2004 supported by the DST, Government of India. He is the reviewer for IEEE Transactions on Evolutionary Computation. He has published over 50 papers in international journals in the area of evolutionary optimization and applications. His research interests include the development of new evolutionary algorithms and applications to engineering optimization problems.
