A Study on the Characteristics of Smoke Control Using Lower Part Pressurization with an Opening in a Large Scale Space

Ju, Hyeon-don · Ahn, Dae-young

Abstract

Smoke control systems of an atrium keep occupants safe from smoke generated during unwanted fires. The two-zone layer interface of the atrium is clearer than small room or corridor. Smoke control in large spaces are achieved using pressurization of the lower layer by mechanical ventilation. The objective of this study are to calculate the inflow and outflow mass rates through the upper and lower opening of the atrium, to study the lower part pressurization with or without the lower opening of the atrium, and to predict the steady-state smoke layer height which the mass outflow rate through the upper opening is more or less equal to the mass rate of fire plume. The smoke layer height are analyzed by FDS developed by the National Institute of Standard and Technology, USA. The part of analyzed results by FDS are compared with the experimental results performed by Yamana and Tanaka. It is known that the lower part pressurization smoke control for the mass flow of the lower opening directing into the atrium from outside were superior to the smoke control directing into the outside from the atrium.

Key words: Atrium, Pressurization, Smoke control, Mechanical ventilation

1. Introduction

In a building an atrium is considered as a large space with openings. The atrium is found in hotels, commercial buildings, and shopping malls. Smoke control systems of the atrium keep occupants safe from smoke generated during unwanted fires. In the atrium most of cooling air through lower opening entrain at the edge of the plume of a fire. Perhaps the smoke layer is at the upper level and the cooling air layer is the lower level of the atrium. The lower interface of the atrium is clearer than small room or corridor. Atrium smoke control and smoke control in similar large spaces are achieved using ventilation system, pressurization system and pressurization and extraction system. Difference in smoke removal rate among the above three smoke control systems was small when an opening was closed (Park, 2003). The smoke production rate (and the required exhaust rate) for the fire in the atrium increases as the heat release rate of design fire increases. Therefore, establishment of design fire is the critical step in design of atrium smoke control systems.

Full scale smoke control experiments have been conducted to investigate the smoke filling behaviors in a large scale space under various smoke control conditions. The experimental results served as the validation study of the simple analytical theories, for example, two-zone model.
The basic idea of lower part pressurization with a lower opening is to increase the smoke exhaustion efficiency of the vents equipped at the upper part of a space by increasing the internal pressure of the space (Yamana and Tanaka, 1985). Calculations have been made for situations where Yamana and Tanaka did not calculate the increase in depth with time (Hinkley, 1988). An overview of the principal design considerations of smoke management systems for covered malls and atria was provided by SFPE Handbook (Milke, 2002). The pressurization system of a room with openings showed less smoke removal rate than the ventilation system and the pressurization and extraction system, and is not recommended for large scale spaces with large openings (Park, 2003). There might be exchange mass flow rate across the interface of smoke layer and cooling air layer in an atrium when a mechanical smoke exhaust system is operating. The mass flow rate across the smoke layer interface can be 30% of the mass exhaust rate of the exhaust system (Chow et al., 2006). The effects of various make-up air supply arrangements and velocities in an atrium smoke management system are examined. Disturbing the fire and smoke plume results in a significant increase in the smoke production rate, as evidenced by a deeper smoke layer (Kerber and Milke, 2007). The effects of vent location, outside temperature, wind velocity and fire size on the performance of natural venting of the vertical vent were numerically investigated using CFAST. The larger fire size becomes, the more mass flow rate through a vent becomes, but the lower interface height of smoke layer becomes (Jeon et al., 2008). Natural smoke exhaust method is preferred when the exhaust vents are located at the ceiling of the atrium. When the smoke exhaust vents are located on the walls of the atrium, the higher positions of the exhaust vents are preferred. And the descending process of the smoke layer is the slowest when the fire source is at the corner of the atrium (Qin et al., 2009). The inflow and outflow mass rates through the doorway located between a burn room and an adjacent room have been researched to predict the neutral-plane of the doorway in the stratified fire cases of the two-room’s enclosure (Ju and Kim, 2012).

Because of the size of the atrium, it is difficult to conduct experiments about smoke control system. Therefore in the large spaces, numerical simulation method play an important role in researching smoke movement and fire phenomena. The one model of the simulation method is two-zone model dividing the fire room into a cooling air layer and a smoke layer. The layers have different uniform properties respectively. The other model is the field model (Computational Fluid Dynamics model) using finite difference method. In our paper the Numerical simulations are performed through the FDS (Version 5.3) computer code developed by NIST. The FDS is a Computational Fluid Dynamics (CFD) model of fire-driven fluid flow. The FDS solves numerically a form of the Navier-Stokes equations appropriate for low-speed, thermally-driven flow with an emphasis on smoke and heat transport from fires. The partial derivatives of the conservation equations of mass, momentum, and energy are approximated by the finite difference method. Turbulent motions are separated into large and small eddy motions in LES. Turbulent eddies that account for most of the large scale motion are large enough to be calculated with sufficient accuracy from the equations of the fluid mechanics. Therefore motion of large eddies is simulated directly, but the small-scale eddy motion is approximated by means of the Smagorinsky form. Two combustion models are used in the FDS. Diffusion of fuel and oxygen are modeled directly for DNS with global one-step, finite-rate chemical reaction. The model is based on the assumption that the combustion is mixing-controlled and that the reaction of fuel and oxygen is infinitely fast (McGrattan et al., 2009; Guan and Kwok, 2009). The schematic drawing of the computational geometry is shown in Fig. 4, which has been made possible by Smokeview, a post-processor graphical-user-interface application (Forney, 2008).

In the natural venting system of the atrium or the lower part pressurization without the lower opening, the outflow mass flow rate through the upper opening is more or less equal to the inflow rate through the fan, but the outflow rate is unequal to the inflow rate in the lower part pressurization with the lower opening of the atrium. The mass flow of the lower opening is directed into outside from the atrium or into the atrium from outside according to the mass flow rate supplied by fan. Thus, the objective of this study are (1) to calculate the inflow and outflow mass rates through the upper and lower opening of the atrium, (2) to study the lower part pressurization with or without the lower opening of the atrium, and (3) to predict the steady-state smoke layer height which the outflow mass flow rate through the upper opening is more or less equal to the mass rate of fire plume. Therefore this study represents the smoke layer heights with various mass flow rates by the fan. And the smoke layer height in the atrium will be calculated if the pressure differences through the upper and lower openings are used. The lower part pressurization smoke control for the mass flow of the lower opening directing into the atrium from outside were superior to the smoke control directing into the outside from the atrium.

2. Lower Part Pressurization with a Vent in a Two-layer Model

In researching the smoke filling process in a large scale space, for examples, an atrium, the two-layer system may be assumed. Consider Fig. 1 showing the atrium that is pres-
surized by mechanical ventilation such as a fan into the lower layer. The atrium with height, \(H_E\) from floor is divided into an upper smoke layer and a lower cooling air layer (Karlsson and Quintiere, 2000). At some time, the upper layer has temperature \(T_E\) and density \(\rho_g\). The mass of the cooling air layer thickness \(z\) from the floor area of the atrium \(A\). The mass of cooling layer is shown as follows:

\[
m_a = \rho_o \cdot A \cdot z
\]  

By forced ventilation into the lower layer the atrium becomes pressurized. This smoke control method not only results in increased pressures across the smoke vents in the upper layer, but also prevents smoke originated outside the space to enter. As shown in Fig. 1, \(\dot{m}_d\) is steady-state mass flow rates into or out of the lower layer, \(\dot{m}_e\) is steady-state mass flow rates out of the upper layer and \(\dot{m}_p\) is plume mass flow rate into the upper layer of the atrium. Mass flow rate from the fan into the lower layer is denoted \(\dot{m}_e\). The plume mass flow rate at the height from the floor of the atrium, \(z\), is given by

\[
\dot{m}_p = k \dot{Q}^{1/2} z^{5/3}, \quad k = 0.2(\frac{\rho_o g}{c_p T_d})^{1/2}
\]  

where \(\rho_o\) is the air density of the cooling layer, \(g\) is the acceleration due to gravity, \(c_p\) is the specific heat at constant pressure, \(T_d\) is the temperature of the cold air layer in the atrium and \(\dot{Q}\) is energy release rate.

The conservation of mass for the cooling air layer can be written as

\[
\frac{d}{dt}(\dot{m}_a) + [\dot{m}_p - \dot{m}_d] - \dot{m}_o = 0
\]  

Combining with Eq. (1), Eq. (3) can be written as

\[
\frac{d}{dt}(\rho_o A \cdot z) + [\dot{m}_p - \dot{m}_d] - \dot{m}_o = 0
\]

The cooling air layer interface height might be kept constant when \(d\dot{m}_d/dt = 0\), \(dz/dt = 0\) and \(d\rho_o /dt = 0\). Then the mass conservation for the lower layer expressed by Eq. (4) is now written as

\[
[\dot{m}_p - \dot{m}_d] - \dot{m}_o = 0
\]  

And for the upper layer as

\[
\dot{m}_p = \dot{m}_e (= \dot{m})
\]

It has been assumed that at steady state the temperature in the smoke layer remains constant. Therefore, the energy release rate produced in the atrium, \(\dot{Q}\), must equal the energy release rate lost due to smoke leaving the smoke layer and the energy release rate lost to the atrium boundaries, that is to say, the ceiling and the walls of atrium that are in contact with the smoke layer, \(A_w\).

\[
\dot{Q} = \dot{m}_e c_p (T_E - T_d) + h \cdot A_w (T_E - T_d)
\]  

where \(a, b\) are the length of the ceiling or the floor respectively when the atrium is a rectangular parallelepiped.

The steady-state mass flow rate through the upper opening, \(\dot{m}_u\), is given as

\[
\dot{m}_u = C_d \rho_o v_d A_d
\]  

where \(C_d\) is flow coefficient and \(A_d\) is an inlet opening area at the lower layer. The velocity of the cooling air through the opening is shown in as follows:

\[
v_d = \frac{\dot{Q} - \dot{m}_u}{\rho_o A_d}
\]  

where \(\Delta P_1\) is pressure difference across the opening at the lower layer. Combining Eq. (9) and Eq. (10), \(\Delta P_1\) is given by Eq. (11) as

\[
\Delta P_1 = \frac{\dot{m}_d^2}{2\rho_o (C_d \cdot A_d)^2}
\]

The steady-state mass flow rate through the upper opening, \(\dot{m}_e\), is given as

\[
\dot{m}_e = C_d \rho_o v_e A_E
\]  

where \(A_E\) is an outlet opening area at the upper layer. The velocity of the smoke through the opening is shown in as follows:

A Study on the Characteristics of Smoke Control Using Lower Part Pressurization...
where $\Delta P_u$ is the pressure difference across the opening at the upper layer. Combining Eq. (12) and Eq. (13), $\Delta P_u$ is given by Eq. (14) as

$$\Delta P_u = \frac{\rho_e}{2} \frac{n_i^2}{C_d \cdot A_e^2}$$  \hspace{1cm} (14)

If $m_o$ is greater than $m_p$, $m_d$ of the lower layer vent were originated from the lower layer to outside. But $m_o$ is smaller than $m_p$, $m_d$ of the lower vent were originated from outside to the lower layer. And it will be discussed three cases as follows:

Case 1: $m_o = m_p = m$, $m_d = 0$, $m_e = m$

Case 2: $m_o < m$ (of Case 1), $m_p = m - m_o$, $m_e = m$

Case 3: $m_o > m$ (of Case 1), $m_p = m_o - m_d$, $m_e = m$

(a) Case 1

Case 1 is similar to natural smoke ventilation with the openings of the atrium. As shown in Fig. 1, the pressure difference across the fan is $\Delta P_f$, and the mass flow rate from the fan is denoted $m_i$. The steady-state mass flow rate through the lower opening, $m_d$, is ignored, $m_d = 0$ because of $m_o = m_p$ and it is assumed in two-layer model that the pressure drop in the lower layer is $\Delta P_f$. The velocity of the cooling air, $v_f$, through the fan is shown in as follows:

$$v_f = \frac{\sqrt{2 \cdot \Delta P_f}}{\rho_a}$$  \hspace{1cm} (15)

Substituting $z_o$ to $z$ and combining $m_o = m_p = m$ in Eq. (2), the steady state height $z_o$ is

$$z_o = \left( \frac{m_o g}{k \cdot Q^{1/3}} \right)^{1/3}$$  \hspace{1cm} (16)

For the upper opening, it is known that the pressure difference can be expressed as $\Delta P_u = (\rho_a - \rho_b)g(H_e - H_N)$, where $H_N$ is neutral plane height. Also, by the smoke layer height, $z_o$ and the pressure drop of the lower layer, $\Delta P_f$, the hydrostatic pressure difference of the upper opening can be expressed as

$$\Delta P_u = (\rho_a - \rho_b)g(H_e - z_o) - \Delta P_f$$  \hspace{1cm} (17)

Combining Eq. (12), (13) and Eq. (17), $m_e$, the mass flow rate through the upper opening is given by Eq. (18) as

$$m_e = C_d \cdot A_e \cdot \frac{\rho_e}{2 \cdot \rho_a} \cdot \frac{\rho_a - \rho_b}{g} \cdot (H_e - z_o) \cdot \Delta P_f$$  \hspace{1cm} (18)

(b) Case 2

In Case 2, as shown in Fig. 2, $m_o$ and $m_d$ are the steady-state mass flow rates into the atrium and $m_e$ is the mass flow rates out of the atrium. It is important that $m_d$ is directed into the lower layer of the atrium from outside. And $m_p = m_o + m_d$ and $m_e = m_o$. Substituting $z_o$ to $z$ and combining $m_p = m_o + m_d$ in Eq. (2), the steady-state height $z_o$ is

$$z_o = \left( \frac{m_o + m_d}{k \cdot Q^{1/3}} \right)^{1/3}$$  \hspace{1cm} (19)

For the upper opening it is known that the pressure difference can be expressed as $\Delta P_u = (\rho_a - \rho_b)g(H_e - H_N)$, where $H_N$ is the neutral layer height. Also, by the smoke layer height, $z_o$ and the pressure drop of the lower layer, $\Delta P_f$, the hydrostatic pressure difference of the upper opening can be expressed as

$$\Delta P_u = (\rho_a - \rho_b)g(H_e - z_o) - (\Delta P_f + \Delta P_e)$$  \hspace{1cm} (20)

Combining Eq. (12), (13) and Eq. (20), $m_e$, the mass flow rate through the upper opening is given by Eq. (21) as

$$m_e = C_d \cdot A_e \cdot \frac{\rho_e}{2 \cdot \rho_a} (\rho_a - \rho_b)g(H_e - z_o) - (\Delta P_f + \Delta P_e)$$  \hspace{1cm} (21)

(c) Case 3

In Case 3, as shown in Fig. 3, $m_o$ is the steady-state mass flow rates into the atrium. But $m_d$ and $m_e$ is the mass flow rates out of the atrium. $m_d$ is directed into outside from the lower layer of the atrium. $m_p = m_o + m_d$ and $m_e = m_o$. 

\[\text{Fig. 2. Schematic Diagram of an Atrium Pressurized by Mechanical Ventilation into the Lower Layer (} m_d = m_o - m_e, m_e = m_p \text{)}\]

\[\text{Fig. 3. Schematic Diagram of an Atrium Pressurized by Mechanical Ventilation into the Lower Layer (} m_d = m_o - m_e, m_e = m_p \text{)}\]
For the upper opening the hydrostatic pressure difference of the upper opening can be expressed as Eq. (22) by the steady-state smoke layer height, \( z_o \) and the pressure drop of the lower layer, \( \Delta P_f - \Delta P_1 \).

\[
\Delta P_u = (\rho_a - \rho_g)g(H_E - z_o) - (\Delta P_f - \Delta P_1) \tag{22}
\]

Combining Eq. (12), (13) and Eq. (22), the mass flow rate through the upper opening, \( \dot{m}_{u_e} \), is given by Eq. (23) as

\[
\dot{m}_{u_e} = C_d A_{u_e} \sqrt{2 \rho_g g (\rho_a - \rho_g)g(H_E - z_o) - (\Delta P_f - \Delta P_1)} \tag{23}
\]

And substituting \( z_o \) to \( z \) and combining \( \dot{m}_p = \dot{m}_{u_e} - \dot{m}_d \) in Eq. (2), the steady state height \( z_o \) is

\[
z_o = \left( \frac{\dot{m}_p - \dot{m}_d}{kQ} \right)^{1/3} \tag{24}
\]

### 3. Numerical Analysis and Results

It were conducted the experiments of smoke control in large scale spaces by Yamana and Tanaka. A atrium was of length 30.0 m, width 24.0 m and height 26.3 m. Therefore, the floor area is 720 m\(^2\). The methanol gas of the burner was supplied at the burning rates of \( 6.67 \times 10^{-2} \) kg/s which are corresponded to the heat release rates of 1300 kW (Yamana and Tanaka, 1985).

In simulation trials, the atrium was of length 30.0 m, width 24.0 m and height 26.3 m, and a large ambient space of length 30.0 m, width 2.0 m and height 26.4 m as shown in Fig. 4. The atrium has the upper opening of width 3.0 m and height 2.2 m and the lower opening of width 6.0 m and height 0.6 m. Also, as shown in Fig. 4, the cooling air for pressurizing the large space was supplied to the lower part of the space through the ducts of width 5.0 m and height 2.0 m on the first floor by operating two fans. The rate of air supply 23.5 m\(^3\)/s (or mass flow rate 29.14 kg/s) and pressure difference 3.41 Pa were obtained based on the flow velocity 2.35 m/s at the duct opening in Test No. D-3 of Yamana and Tanaka' experiments (Yamana and Tanaka, 1985).

Numerical experiments were conducted for different methanol gas supplies. A square diffusion burner supplied with methanol of size 180 cm \( \times \) 180 cm was used as the fire source on the floor of the space. The burner was located at the center of the atrium. The methanol gas of the burner was supplied at the burning rates of \( 3.33 \times 10^{-2} \) kg/s, \( 6.67 \times 10^{-2} \) kg/s and \( 9.99 \times 10^{-2} \) kg/s which are corresponded to the heat release rates of 650, 1300 and 2600 kW, respectively (Yamana and Tanaka, 1985).

As shown in Figs. 4 and 5, the minimum grid size of 0.2 m was used in simulations. A three-dimensional Cartesian coordinates were assigned with \( x, y, z \). In atrium, the numbers of cells along \( x, y \) and \( z \) directions are 150, 120 and 132, respectively and the total number of the cells is 2,376,000 (= 150 \( \times \) 120 \( \times \) 132). In the outside of the atrium, the numbers of cells along \( x, y \) and \( z \) directions are 150, 10 and 132, respectively and the total number of the cells is 198,000 (= 150 \( \times \) 10 \( \times \) 132).

The boundary conditions for the walls, ceiling and floor of the atrium are shown as Table 1. The ceiling and floor are specified as concrete and all of the walls are specified as gypsum board. Ambient temperature and pressure are 12.5°C and 101.325 kPa, respectively. Environmental space

is extended 2.0 m outside the atrium. In the space, zero gradients for velocity and temperature are given, and pressure also given the ambient pressure.

The data of the smoke layer height produced from the temperature examined by thermocouple and the observation by eye are plotted in Fig. 6. Also, the smoke-filling curve shown by the dotted line is referred to as the “standard filling” curve by Yamana and Tanaka. According to the results in Fig. 6, the smoke layer height predicted by FDS almost agrees with the layer height examined by thermocouple. As can be seen, the descent of the smoke layer is very quick at first but slows down later because the rate of air entrainment from the lower layer decreases as the smoke layer descends.

Fig. 7 also shows the temperature measured at heights of 8 m, 16 m and 24 m. In two-zone model analysis assuming a constant average value of the smoke layer, for examples, a smoke temperature, is reasonable because the temperature increases of 16 m and 24 m are relatively low. At height of 8 m, simulation value and experimental value is occurred much more differently. But the simulation value at height of 5 m is similar to the experimental value at height of 8 m.

As shown in Fig. 8, the temperatures of the upper smoke layer and lower cooling air layer of two-zone model analyzed by FDS are revealed in the case of the fire size of 1300 kW. It is reasonable in two-zone model that the temperatures of the upper layer and lower layer are assumed...
25°C and 12.5°C, respectively. Also, Fig. 9(a), (b) and (c) are revealed in the case of the fire size of 1300 kW. Fig. 9(a) shows the volume flow rates of the upper and lower opening analyzed by FDS. The pressure differences of the upper and lower opening are given by Eq. (11) and Eq. (14) and are shown in Fig. 9(b). The smoke layer height is given by Eq. (24) and is analogous to the height analyzed by FDS as shown in Fig. 9(c) (Yamana and Tanaka, 1985; Karlsson and Quintiere, 2000).

Fig. 10 shows the mass flow rates of the lower opening, which were gotten by simulation tests varying the air supply rate of the fan in the fire size of 1300 kW. The lower and upper openings were activated in 180 sec and 210 sec, respectively. \( \dot{m}_o \) is the mass flow rate from the fan into the lower layer and the mass flow rate ratios are given by \( S = \dot{m}_o / 23.5 \) (m³/sec). The mass flow rates of the lower opening is always directed into outside from the atrium in case of \( S = 1, 1.25 \) and \( 1.5 \) and into the atrium from outside in case of \( S = 0, 0.25 \) and \( 0.5 \). In case of \( S = 0.75 \), at the first time the mass flow rates is directed into outside but later is directed into the atrium. Fig. 11(a), (b) and (c) are revealed in the case of the fire size of 1300 kW. Fig. 11(a) shows the smoke layer heights in case of \( S = 1, 1.25 \) and \( 1.5 \) and Fig. 11(b) shows the smoke layer heights in case of \( S = 0, 0.25, 0.5 \) and \( 0.75 \). Also, Fig. 11(c) accurately shows the smoke layer heights in \( S = 0, 0.25, 0.5, 0.75, 1, 1.25 \) and \( 1.5 \). It is known that the lower part pressurization smoke control for the mass flow of the lower opening directing into the atrium from outside were superior to the smoke control directing into the outside from the atrium. Especially, that is to say, the case of \( S = 0 \) is natural venting. As shown in Fig. 7 and Fig. 11(c), the natural venting activating the lower and upper openings after pre-flashover fire elapse is recommended.

The atrium not having the lower opening is modeled and analyzed by FDS. As shown in Fig. 12, the smoke layer height of the atrium not having the lower opening is compared with the height of the atrium having the lower opening in the case of the fire size of 1300 kW. Fig. 12 shows both smoke layer heights are alike.
The smoke layer heights of the three fire sizes of 650 kW, 1300 kW and 2600 kW are shown in Fig. 13, respectively. The heights analyzed for 2600 kW almost agree with the heights for 1300 kW. But the smoke layer for 650 kW are a little higher than the smoke layers for 1300 kW and 2600 kW.

4. Conclusions

When a fire was happened in the atrium, the smoke layer heights were analyzed numerically by the FDS. The descent of the smoke layer is very quick at first but slows down later. The smoke layer height predicted by FDS almost agrees with the layer height examined by thermocouple.

The lower part pressurization smoke control for the mass flow of the lower opening directing into the atrium from outside were superior to the smoke control directing into the outside from the atrium. And the natural venting activating the lower and upper openings after pre-flashover fire elapse is recommended.

The smoke layer height of the atrium not having the lower opening is similar to the height of the atrium having the lower opening. And the smoke layer heights analyzed for the fire size of 2600 kW almost agree with the heights for the fire size of 1300 kW.
