Received August 22, 2005; Accepted October 21, 2005

Among 24 isolates of fluorescent Pseudomonads, 5 isolates named as LPT1, LPT2, LPT3, LPT4 and LPT5 were screened *in vitro* for their nematicidal activity against cyst forming nematode, *Heterodera cajani* causing patchiness, poor and stunting growth besides discoloration in *Sesamum indicum*. Second stage juveniles of *H. cajani* hatched from egg masses were collected from roots of host plant and subjected to fresh and heat-treated culture filtrates of isolates for 24 h. Mortality of *H. cajani* was recorded on the basis of parameters used for test organism bioassay. Among these isolates, *Pseudomonas aeruginosa* LPT5 caused maximum mortality towards second stage juvenile of *H. cajani* in *in vitro*. Five isolates were used as seed coating for the management of cyst forming nematode *H. cajani* on sesame in greenhouse condition. The strain LPT5 was better than the other strains in reducing the population of *H. cajani* both in *in vitro* and *in vivo*. The reduction in cyst and juveniles population was found to be 49 and 60%, respectively when seeds were coated with strain LPT5. Among other strains, LPT4 was also found to inhibit the cyst and juveniles population 12 and 36% respectively. Increases in early vegetative plant growth parameters recorded in both *in vitro* and *in vivo* further revealed the significance of indigenous bacteria in comparison to introduced strain.

**Key words:** *Heterodera cajani*, *Pseudomonas aeruginosa*, *Sesamum indicum*, nematicides

---

**Materials and Methods**

**Nematode culture.** Pure inoculum of the nematode culture *Heterodera cajani* was obtained from Department of Plant Protection, Aligarh Muslim University, Aligarh, India and was maintained by allowing it to multiply on pigeon pea (*Cajanus cajan*). A number of culture pots were raised and maintained for further studies.

**Bacterial culture.** The fluorescent Pseudomonads strains (LPT1, LPT2, LPT3, LPT4 and LPT5) were isolated from the rhizosphere of the mature tomato (*Lycopersicon esculentum*). Appropriate serial dilutions of soil suspension in sterile water were spread on Nutrient agar medium (NAM) supplemented with 100 µg·mL⁻¹ streptomycin to evaluate the antibiotic resistant strain, and the plates were incubated at 28 ± 1°C for 24-48 h. The fluorescent pigment producing bacterial colonies were carefully picked up and pure culture was kept in NAM slants at 4°C. Morphological and biochemical properties of the bacterial strains were carried out as outlined earlier. Plant growth promoting activities in fluorescent pseudomonads were determined by growing log phase (24 h old) culture of different strains of pseudomonads. The production of siderophore was estimated qualitatively on Chrom-Azurol S agar medium (CAS), a universal medium for siderophore detection according to Schwy n and Neilands. For this, the strains were separately spotted on CAS agar medium and plates were incubated at 28 ± 1°C for 48 h. Production of

Hydrocyanic acid production (HCN) was determined by the modified method of Miller and Higgins\textsuperscript{11} while Indole acetic acid (IAA) production was observed according to Gupta \textit{et al.}\textsuperscript{9}.

\textbf{In vitro interaction between juveniles and bacterial culture filtrate.} Healthy cyst along with egg masses of \textit{H. cajani} were kept in petri plates containing sterilized water in the incubator at 29°C for hatching. The active second stage juveniles (J2) were collected and stored in refrigerator at 4°C for further use in the experiment. Bacterial strains were grown in Erlenmeyer flasks containing Nutrient Broth (NB) at 28°C. After 24 h, the bacterial culture was centrifuged at 7000 g for 15 min at 4°C to obtain cell free culture filtrate. The bacterial pellet was used for seed bacterization. To determine the effect of culture filtrate (CF) on juveniles of \textit{H. cajani}, 2 ml of bacterial culture filtrate were transferred in cavity glass slide in which 1 ml juveniles (40-45 surface sterile Juveniles/ml) were added in quintuplicate. The numbers of dead juveniles were counted and mean percentage of the dead larvae was observed after 12 and 24 h.\textsuperscript{12} The culture filtrates were heat-treated by boiling in water bath for a period of 5 min and subsequently tested for the nematocidal activity as described by Ali \textit{et al.}\textsuperscript{2}.

\textbf{Seed bacterization.} The bacterial pellets were washed with sterile distilled water (SDW) and re-suspended in SDW to obtain a population density of \(1 \times 10^8\) CFU·ml\(^{-1}\). This suspension was mixed with 1% carboxymethylcellulose (CMC) solution. The surface of sterilized seeds (0.5% mercuric chloride) were coated with the slurry and allowed to air-dry overnight in aseptic condition. Bacterized and non-bacterized sesame seeds were sown separately in 21 cm diameter pots containing 2.5 kg steam sterilized soil (77.3% sand, 13.6% silt, 11.7% clay, 0.097% total organic C, pH 6.4 and 36% water holding capacity) in seven sets of treatments: i) \textit{H. cajani} and \textit{Pseudomonas aeruginosa} LPT1, ii) \textit{H. cajani} and \textit{P. aeruginosa} LPT2, iii) \textit{H. cajani} and \textit{P. aeruginosa} LPT3, iv) \textit{H. cajani} and \textit{P. aeruginosa} LPT4, v) \textit{H. cajani} and \textit{P. aeruginosa} LPT5, vi) \textit{H. cajani} and \textit{P. aeruginosa} MTCC 1934, and vii) \textit{H. cajani} alone. After one-week of seedling emergence, each pot was inoculated with 1000 freshly hatched second stage juveniles of \textit{H. cajani}. The inoculation was done with second stage juveniles of \textit{H. cajani} by pouring aqueous suspension of the nematode in four soil cavities (2-3 cm deep) around the collar of the seedling. The holes were then tempted shut and the plants were maintained. The influences of treatments in plant growth characters and nematode population were recorded after 90 days. Pots were arranged in a randomized block design on a bench in a green house. Care of plants was taken as needed. Each treatment was replicated five times.

\textbf{Root colonization.} After 90 days of sowing, count on

Bacterial root colonization from 1 g root was recorded by serial dilution plate technique by grinding the root bits. A dilution of the suspension was poured on NAM supplemented with 100 µg ml⁻¹ streptomycin to evaluate the population of Pseudomonas aeruginosa\textsuperscript{MTCC}. After 24 h of incubation at 28 ± 1°C, CFU's per gram root was counted.

**Results and Discussion**

A total of 24 strains of fluorescent pseudomonads were isolated from the rhizosphere of the mature tomato, out of which 5 strains of pseudomonads LPT1 to LPT5 were screened as the most promising strains for their nematocidal activity. The strains were motile, Gram-negative, aerobic and non-spore forming rods. The colonies were smooth, translucent, large, low convex and 2-4 mm in diameter with regular spreading edge after 24 h incubation at 28 ± 1°C. The strains were oxidase, catalase, urease and gelatin hydrolysis positive. Greenish blue (Pyocyanin, Hi Media, MU119) and yellow fluorescent pigments were produced on Pseudomonas agar (fluorescein, Hi Media, MU120) by the isolates which identified as Pseudomonas aeruginosa and confirmed with the evidences, while comparing with known strain of Pseudomonas aeruginosa MTCC strain 1934 (Table 1). Strain LPT5 produced more fluorescent pigment, siderophore, HCN and IAA in comparison to that of other isolates and also showed antagonism against Fusarium oxysporum, a dreaded pathogen causing wilt of sesame (Table 2).

In this study, we found that the strain LPT5 showed maximum nematocidal effect against the second stage juveniles of H. cajani. Strain LPT5 strain showed maximum juvenile mortality of 45 and 65% after 12 and 24 h, respectively, whereas strain LPT4 showed minimum juvenile mortality of 27 and 35% after 12 and 24 h, respectively. The data revealed significant difference in mortality, after an exposure period of 24 h, in all the Pseudomonas strains as compared to control. Nematode mortality increased at the increase in the exposure time. Whereas, the nematocidal activity was lost considerably.

in heat-treated culture filtrate (Table 3). This indicated the extra-cellular and heat-sensitive nature of nematicidal substance of the *P. aeruginosa*.

Seeds coated with bacterial pellet showed significant increase in plant growth characters in comparison to that of non-bacterized seeds. The maximum increase in shoot and root length, fresh and dry weight of shoot and root was recorded in seedling raised with LPT5 bacterized seeds as compared to control (non bacterized) as shown in Table 4.

The final cyst and J2 population in soil were significantly reduced when the seeds were treated with *Pseudomonas* as compared to control (nematode alone) (Fig. 1 and Fig. 2). The maximum reduction in cyst and J2 population was 49 and 60% respectively, in treatment that received bacterized seeds with LPT5 in comparison to control. The minimum reduction in cyst and J2 population was 12 and 36%, respectively when the seeds were treated with LPT4. Maximum colonization (3.8 × 10⁵ CFU·g⁻¹ root) of rhizobacterium in roots was observed in seeds treated with isolate LPT5 (Table 4).

The strains LPT1 to LPT5 identified as fluorescent pseudomonads belong to *Pseudomonas aeruginosa*. The

identification of the strains was made on the basis of their morphological and biochemical properties such as siderophore, HCN, and IAA production and these strains showed blue green fluorescent color due to the presence of pyocyanin pigment. The strain LPT5 inhibits the wilt causing Fusarium oxysporum. Earlier, Kumar et al. reported that the strain PE30 reduces the root disease complex due to root knot nematode, Meloidogyne incognita and wilt disease causing F. oxysporum and promote the growth of tomato. Fluorescent pseudomonads are known to have a significant role in the suppression of fungal pathogen via the production of antifungal metabolites whereas these rhizobacteria reduced the hatching and also invasion due to the production of toxic metabolites, nematicidal components and alteration of specific root exudates that altered nematode behavior. Our results showed that the culture filtrate of the Pseudomonas aeruginosa isolates caused significant juveniles mortality due to their nematocidal nature. Earlier, nematocidal activity in some strains of Pseudomonas was reported. Enhanced larval mortality of M. incognita and H. cajani were reported when the juveniles exposed to culture filtrate of Bacillus subtilis and P. fluorescens. The plant growth parameters such as length, fresh and dry weight of shoots and roots were also significantly improved in plant treated with P. aeruginosa strains. Similar increase in plant growth parameters in Pseudomonas treated plants was reported in potato and tomato. Such direct increase in plant growth may be due to production of IAA by Pseudomonas mediated IAA activity and indirectly due to production of siderophore. The effectiveness of P. aeruginosa as a potential biocontrol agent may involve more than one attribute against H. cajani. Oostendorp and Sikora reported that the sugar beet cyst nematode penetration to sugar beet was decreased due to P. aeruginosa treatment. One of the large varieties of antibiotics produced by fluorescent pseudomonads, 2, 4-diaceyctyl phloroglucinol and chitinases reduced juveniles mobility and delayed egg hatch of the potato cyst nematode, Globodera rostochiensis. But other factors such as ability of fluorescent pseudomonas to envelop or bind the root surface lectins, thereby interfering with the normal host recognition by the nematode can not be ruled out. Santhi and Sivakumar attributed the best control of plant parasitic nematodes by fluorescent pseudomonads to its best colonizing ability. Root colonization by rhizospheric bacteria has been reported to reduce nematode invasion thereby protecting the roots during early development stages of the plant.
