The relative intensity noise (RIN) characteristics in 405 nm blue laser diodes grown on wurtzite AlGaInN multiple quantum well structures were investigated using the rate equations with the quantum Langevin noise model. The device parameters were extracted from the optical gain properties of the MQW active region using the self-consistent numerical method developed for calculating the multiband Hamiltonian in the strained wurtzite crystal. These methods have been applied to laser diodes for various conditions including the external feedback and the high frequency current injection.

I. INTRODUCTION

It is well known that the GaN-based semiconductors are the best material for short wavelength devices. Especially, the quaternary alloy AlGaInN has wide band gap energy, varying with the composition and almost covering the visible spectrum while extending to the ultraviolet region. So, technologies of nitride semiconductors have led to the development of electrical devices for applications of high power and high frequency such as optical data storage and mobile communication. In these applications, the blue laser diodes have become important building blocks for the next-generation optical data storage elements and optical recording systems. However, their performance sometimes lags behind the demand required for a fast data access time and operation speed. Such limitations are imposed in part by the noises of the laser diodes used in the optical pick-ups [1]. In this paper, characteristics of such an intensity noise, known as the relative intensity noise (RIN), were analyzed for nitride compound semiconductor laser diodes. The primary source of the intensity noise in the semiconductor laser diode is the spontaneous emission that is usually amplified due to the external feedback from the optical disks. Such quantum noise has been modeled using the quantum Langevin formalism [2]. The required material parameters have been extracted by using the self-consistent Poisson-Schrödinger and the multiband Hamiltonian for strained wurtzite crystals [3,4]. To show the validity of this method, the simulation results were compared to the analytic solutions when the external feedback effect is ignored, which shows a good agreement. If the optical utilization efficiency is too high, however, relative intensity noise (RIN) generated by the blue-violet laser diode during play will interfere with play. This problem is being avoided by using different optical utilization efficiencies for play and record. One of the factors behind RIN is quantum noise, so that RIN increases as laser diode optical output decreases. In general, reducing the optical output of a blue-violet laser diode to low power will cause RIN to exceed the -125 dB/Hz level accepted as the limit for disc play. This would push RIN over -125 dB/Hz, making playback difficult. So, one way to reduce the external feedback effect is to modulate the injection current to the laser cavity up to a certain high frequency [1,3]. Although the technique of high-frequency injection (HFI) can solve this problem, the proper modulation frequency must be chosen practically. In this work, the optimum conditions for the high frequency current injection noise
reduction method on the RIN characteristics has been investigated to reduce the external feedback effect that is inevitable in DVD-ROM or RW pick-up systems.

II. SELF-CONSISTENT ANALYSIS OF THE STRAINED BLUE LASER DIODE

The 405 nm laser diode under investigation has typical AlGaInN MQW active structures as shown in Figure 1. The quantum well regions are 3 nm In0.12Ga0.88N and the barrier regions are In0.02Ga0.98N. The SCH regions are Al0.2Ga0.8N and the cladding regions are N- and P-doped Al0.33Ga0.67N sandwiched by GaN ohmic contact layers [5,6].

Figure 2 (a) shows the energy band diagram of multiple quantum well (MQW) and electron blocking layer (EBL) and (b) shows E-k band diagram and Density of States (D.O.S.) of conduction and valence band. For the enhanced optical performance, P-doped Al0.3Ga0.7N EBL is indispensable for the suppression of electron overflow from the active layer to the p-type cladding layer. The gain and spontaneous emission spectra of the AlGaInN 3 QW LD are obtained by numerical analysis of self-consistent Poisson equations and the Hamiltonian equations for multiband strained wurtzite multiple quantum well structures [7]. Figure 3 (a) and (b) show the variation of the optical gain properties due to the strain effects. The compressive strain effect led to a 5 nm blue shift in the emission spectra and enhanced optical performance such as gain and differential gain. The strain effects due to the lattice constant smaller than GaN in the buffer layer affects the differential gain. Figure 4 (a) and (b) show the calculated gain spectra and the spontaneous emission spectra from the AlGaInN 3 quantum well structures when the injection carrier density varies from 1.8×10^{19}/cm^3 to 5.0×10^{19}/cm^3 by the step of 1.6×10^{12}/cm^3. All relevant simulation parameters, such as the transition energy E_T, the Fermi energy separation versus the injection carrier concentration E_{Fp}, the population inversion parameter n_{sp}, the transparency carrier concentration N_{tr}, the maxi-

III. RELATIVE INTENSITY NOISE ANALYSIS OF LASER DIODE

The quantum noise due to the external feedback from the optical disc surface into the laser cavity is modeled as shown in Fig. 1. F and R shown in the figure denote the forward and reverse traveling optical fields, \( r_{ext} \), \( \phi_{ext} \), \( L_{ext} \) the reflection coefficient, phase retardation, and the length of the external cavity, respectively. The quantum noise has been modeled with the quantum Langevin formalism and the required material parameters have been extracted by using the self-consistent Poisson and the multiband Hamiltonian. The relative intensity noise (RIN) of the laser diode is defined as the ratio of the laser intensity noise \( \delta P(t) \) to the average laser power \( P_0(t) \), or

\[
\text{RIN} = \frac{S_P(\omega)}{P^2} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \delta P(t+r) \delta P(t) e^{-i\omega r} \, dr
\]  

The characteristics of the laser intensity noise can be obtained by analyzing the rate equations:

\[
\frac{d}{dt} N(t) = \frac{I(t)}{q} + \frac{N(t)}{\tau_e} - G(t) P(t) + F_N(t)
\]  

\[
\frac{d}{dt} P(t) = (G(t) - \gamma) P(t) + R_{sp} + 2 \chi P_{ph} + F_P(t)
\]  

\[
\frac{d}{dt} \phi(t) = \frac{1}{2} \alpha (G(t) - \gamma) - \frac{n_e}{n_g} (\omega - \Omega) + \chi \phi_{ph} + F_{\phi}(t)
\]
with

\[ P_{\text{fb}} = \sqrt{P(t)P(t-\tau)\cos[\omega \tau + \phi(t) - \phi(t-\tau)]} \]  
\[ \phi_{\text{fb}} = \sqrt[3]{\frac{P(t-\tau)}{P(t)}} \sin[\omega \tau + \phi(t) - \phi(t-\tau)] \]  
\[ \text{(5)} \]
\[ \text{(6)} \]

where \( N(t), P(t), \phi(t) \) and \( I(t) \) denotes the carrier density, the photon density, the instantaneous phase and current in the cavity of LD. \( G(t) \) is the optical gain, \( R_{\text{sp}} \) is the spontaneous emission rate, \( \gamma \) is the optical loss, \( \gamma_{\text{m}} \) is mode refractive index, \( n_g \) is the group refractive index, \( F_i \) is the Langevin noise factors [8], \( \chi \) is the external feedback coefficient, and \( \tau \) is the round trip time for the external cavity, respectively [9]. Random fluctuations of the lasing frequency are caused by carrier density noise and by the phase noise. The other parameters follow conventional notations. The Langevin noise functions show characteristic behaviors as following:

\[ \langle F_i(t) \rangle = 0 \quad \text{for} \ i = P, N, \phi \]  
\[ \langle F_i(t) F_j(t') \rangle = 2D_{ij}\delta(t-t') \quad \text{for} \ j = P, N, \phi \]  
\[ 2D_{pp} = 2n_{pp} \frac{P}{\tau_P} \]  
\[ 2D_{NN} = 2n_{pp} \frac{\overline{N}}{\tau_P} + \frac{N}{\tau_e} \]  
\[ 2D_{P\phi} = -\frac{n_{pp}}{\tau_P} \]  
\[ 2D_{\phi\phi} = n_{pp} \frac{1}{2P} \tau_P \]  
\[ \text{(7)} \]
\[ \text{(8)} \]
\[ \text{(9)} \]
\[ \text{(10)} \]
\[ \text{(11)} \]
\[ \text{(12)} \]

Here, \( \overline{N}, \overline{P} \) are the averages of \( N, P \) in the steady state, \( \tau_P \) is the photon lifetime, \( \tau_e \) is the electron lifetime and \( n_{pp} \) is the population inversion factor [8]. The optical gain in (2) can be expressed in terms of differential gain as:

\[ G = \frac{dG}{dN} \frac{(N - N_{tr})}{1 + \varepsilon^P} = \frac{G_N (N - N_{tr})}{1 + \varepsilon^P} \]  
\[ \text{(13)} \]

Here, \( G_N \) is the differential gain, \( N_{tr} \) the transparency carrier concentration, and, \( \varepsilon \) the gain suppression coefficient.

IV. SIMULATION RESULTS

In the time domain analysis, the Langevin noise functions were implemented by random number generators with amplitude proportional to the square root of the diffusion coefficients. Figure 5 shows the RIN characteristics of the 405 nm blue laser diode. This shows the Fourier transformed spectra of the noise terms for various optical output power levels of the laser diode. The numerically obtained RIN spectra show a good agreement with the analytic solutions as shown in dashed lines.

Figure 6 shows the numerical simulation results of the RIN spectra when the external feedback is non-negligible. This result was compared to -125 dB/Hz, which is the RIN requirement of the commercial optical pick-up system. When the external feedback rate is smaller than 0.01%, the RIN decreased drastically as the power of LD increased. When the external feedback rate is over 1%, the RIN characteristics deteriorates beyond use. We can see any external feedback rate larger than 0.1% would result in the RIN to be higher than -125 dB/Hz. These results indicate that the RIN decreases as the laser power increases. However, the low power LD performance plays a key role in the optical pick-up system since the majority of the operation is in the reading mode.

So, one way to reduce the external feedback effect is modulating the injection current to the laser cavity up to a certain frequency [10,11]. Figure 7 shows the driving method of a laser diode with a high frequency current superimposition to reduce the RIN. The reference value of the modulation current \( I_{\text{mod0}} - I_{\text{bias}} \) is the margin between the bias current \( I_{\text{bias}} \) and the threshold current \( I_{\text{th}} \). It is worth to note that when the injection current becomes smaller than the threshold by a large modulation depth, i.e., \( I_{\text{mod0}} - I_{\text{bias}} > I_{\text{bias}} - I_{\text{th}} \), the RIN characteristics deteriorate significantly. Figure 8 (a) shows the low frequency RIN characteristics at the injection current bias levels for 10 mW with different modulation depths. Fig. 8 (a) shows the RIN result when the modulation depth is 1 \( I_{\text{mod0}} \), while Fig. 8 (b) when...
The larger modulation depth gave the RIN characteristics with 1–2 GHz modulation frequency is above -125 dB/Hz, while the smaller modulation depth gave the RIN characteristics at the similar frequency under -125 dB/Hz. In this case, despite the fluctuation due to random signal, the optimum modulation frequency turned out to be around 5–6 GHz and the RIN reduction of more than 8 dB/Hz was obtained. Figure 9 shows the RIN characteristics for 5 mW output power. Figure 9 (a) shows RIN results when the modulation depth is 1 \textbf{mod}0, while Figure 9 (b) when 0.5 \textbf{mod}0. From Fig. 9, one can once again see that it is more favorable to use a smaller modulation depth for a RIN reduction. In this case, a RIN reduction of more than 10 dB/Hz could be available by optimizing the injection modulation frequency around 3–4GHz, and optimizing the modulation depth as well.

V. CONCLUSIONS

In this work, the relative intensity noise characteristics in 405 nm laser diodes grown on wurtzite InAlGaN multiple quantum well structures were investigated using

![FIG. 7. Driving method of a laser diode with a high frequency current superimposition.](image)
the rate equations with the quantum Langevin noise model. The device parameters were extracted from the optical gain properties of the MQW active region using the self-consistent Poisson equation and the multiband Hamiltonian for the strained wurtzite crystal. The simulation results indicate that the critical external feedback for -125 dB/Hz RIN is less than 0.1% and it becomes more severe as the LD power decreases as in the reading mode. To alleviate the external feedback effect on the RIN characteristics, we proposed a new method by optimizing the modulation depth as well as the frequency of the high frequency current injection to be superimposed to the DC bias current of the LD. We have shown that the high frequency injection method could improve the RIN by more than 10 dB/Hz at an optimized frequency and modulation depth.
